Bunching of the mucosa is a potential pitfall in patients with an overprojected tip or hanging columella. Wide undermining of the flaps around the nasal spine allows the mucosa to be moved superiorly and nearly always precludes the need to resect mucosa or vestibular skin. Fixation of the medial crura in this manner provides excellent support for the nasal tip. It also affords precise control of the tip projection, rotation, and alar–columellar relationship without having to excise mucosa or estimate the amount of postoperative tip settling. This maneuver is suited to patients with a tension-nose deformity, overprojected tip, underprojected tip, or hanging columella. If using this technique, the surgeon must avoid creating a retracted columella, obtuse columella-labial angle, or overrotated nose. These pitfalls can be avoided by restricting this technique to those patients who have an inappropriately long caudal septum that would otherwise need to be trimmed.

Alternately, if the caudal septum is short or of appropriate length but tip position must be altered or stabilized, a caudal extension graft can be used to create a septum long enough to bind to the medial crura in the midline (7). This is a graft that can be sutured end to end or overlapped with the caudal septum, depending on whether it is in the midline. End-to-end grafts are stabilized with extended spreader grafts (Figs. 182.16 and 182.18) or two sets of bilateral splinting grafts sutured with 5-0 PDS sutures. Another suture through the periosteum of the anterior nasal spine greatly improves the sturdiness of an inline graft. A slightly deviated caudal septum can be lengthened with an overlapping graft. The graft is secured to the caudal septum with horizontal mattress sutures. Regardless of the technique used, the caudal margin of the graft should be in

Figure 182.18 Inline caudal extension graft with splinting cartilage grafts.

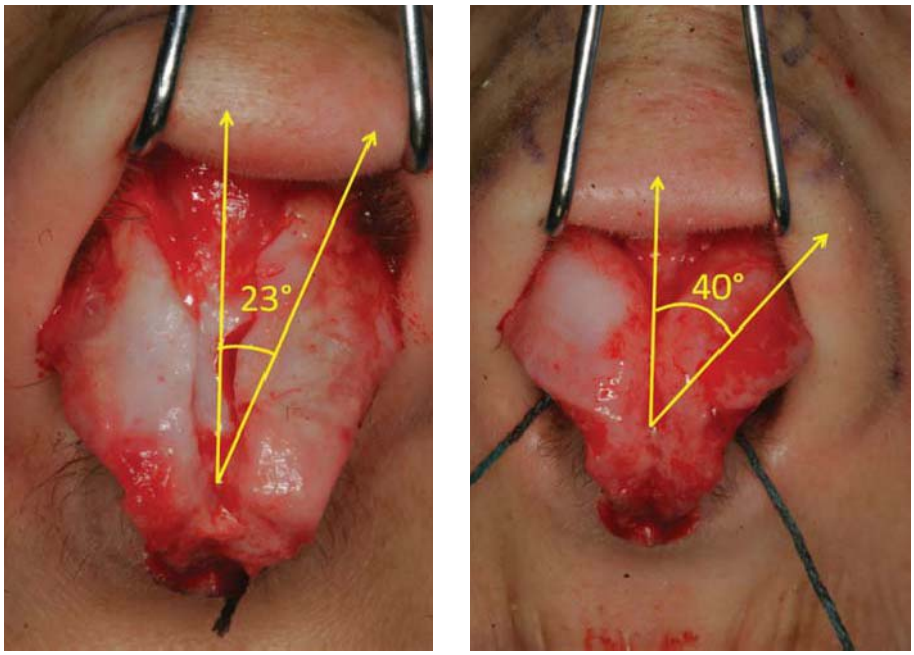

Figure 182.19 The ideal lateral crura are positioned so that they are pointing toward the lateral canthi (35 to 45 degrees off midline). Lateral crura that are oriented less than 30 degrees off of midline will tend to create a fullness in the transition point between the tip and supratip and in some patients may present with a parentheses deformity.

the midline. The lengthening of the caudal septum allows suture fixation of the medial crura to the graft to stabilize the nasal base. End-to-end grafts are preferred because they are less likely to cause deviation or airway obstruction (4). Orientation of the caudal extension graft is an important detail in its placement. If the graft is trapezoidal and has its longer edge posteriorly, it will help to open an acute nasolabial angle. A longer anterior edge will counter rotate the tip. A rectangular graft is helpful in correcting a retracted columella.

Nasal Tip Surgery

Once a solid foundation has been created at the nasal base, the tip can be modified. Following is a brief overview of some common structural techniques for improving the aesthetic contour and proportions of the nasal tip. The most important step of nasal tip surgery is the accurate assessment of the tip structures and their contribution to the tip shape. It is important to note the horizontal (dome to dome) and vertical (caudal margin to cephalic margin of the lateral crura) contributions to the tip bulbosity (1). The surgeon must also assess whether the lateral crura are oriented properly. The ideal lateral crura are positioned so that they are pointing toward the lateral canthi (35 to 45 degrees off midline) (1). Lateral crura that are oriented less than 30 degrees off of midline will tend to create a fullness in the transition point between the tip and supratip and in some patients may present with a parentheses deformity (Fig. 182.19).

If the tip cartilages are too wide in the vertical plane with normally positioned crura, there will be supratip fullness on lateral view. This can be corrected with a conservative cephalic trim of the lateral crura, leaving 8 to 10 mm of the lateral crus (4) (Fig. 182.20). The cephalic trim should be performed medially because this is the area that contributes to a bulbous tip. Trimming laterally will have little effect on the tip and will only weaken the nasal sidewall, risking supra-alar pinching with scar contracture over time (4).

Once the appropriate vertical dimensions of the nasal tip are achieved, the horizontal dimensions can be addressed. Dome-binding sutures are an excellent way to decrease horizontal width of the nasal tip in primary

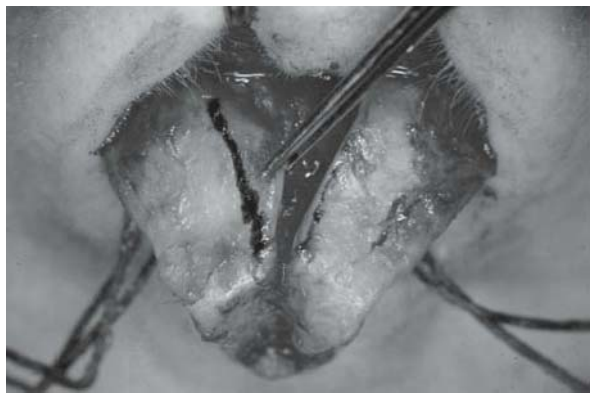

Figure 182.20 Medial-cephalic reduction of the alar cartilages, maintaining a generous residual complete strip.

rhinoplasty patients (Fig. 182.21). Using two separate dome sutures is usually preferred over a single transdomal suture, to prevent pinching of the domes together (Fig. 182.22) (1,4). The sutures are placed in a horizontal mattress fashion with the knots medially between the domes. Caution must be exercised to prevent bringing the domes too close together, as this will cause flattening of the double break on lateral view, and an excessively narrow tip with vertical orientation of the normal horizontal orientation of the nasal tip highlight (4). This will therefore give an unnatural appearance to the nasal tip. Dome sutures also have effects laterally on the lateral crura. The objective is to create flat lateral crura that will provide the desired contour between the tip lobule and the lateral alae. If the crura do not flatten properly but instead buckle or deform with placement of the suture, this can cause pinching at the junction between the tip lobule and the alar lobule. In this case, the lateral crus can be

Figure 182.21 Narrowing of the tip with dome-binding sutures **(A,B,C)** before and **(D,E,F)** after procedure.

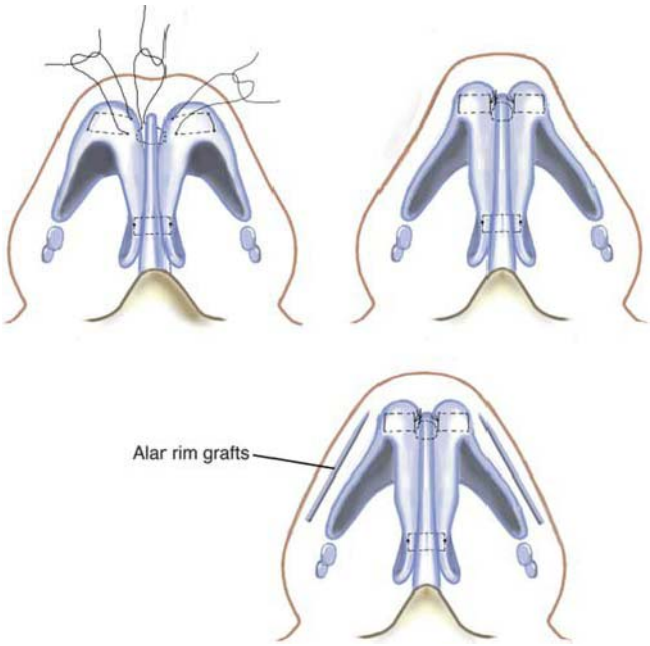

Figure 182.22 Separate dome-binding sutures are applied as shown with the knots tied between the domes. In many cases a separate interdomal suture is placed to bring the domes closer together. If necessary alar rim grafts can be placed to eliminate any pinching of the nasal tip.

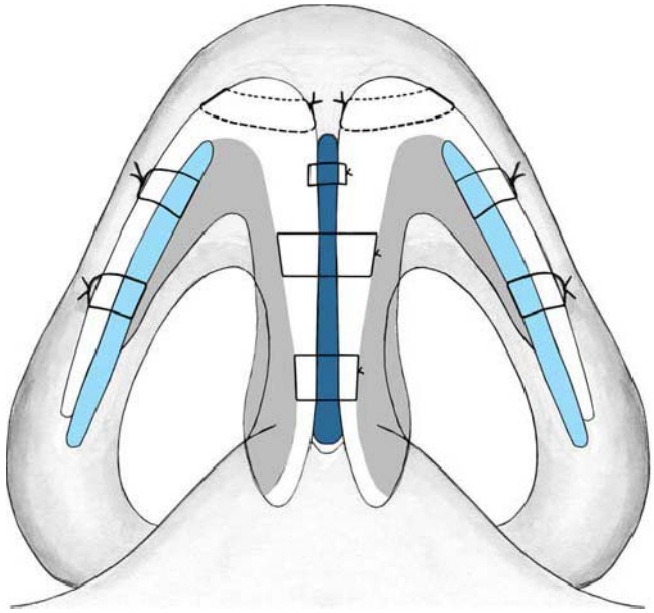

Figure 182.23 Lateral crural strut grafts (*light blue*) are placed between the undersurface of the lateral crura and the vestibular skin. The graft acts to flatten the bulbous lateral crura and also support the lateral wall of the nose. After positioning the lateral crural strut grafts bilateral dome-binding sutures are placed to set tip width.

strengthened and straightened by suturing a lateral crural strut graft onto its undersurface (Fig. 182.23) (4). This prevents nasal obstruction and creates a smooth triangular shape to the nasal base.

Lateral crural strut grafts can be used to accomplish several goals (8). They are useful in flattening lateral crura that are bulbous or intranasally blocking the internal airway (Fig. 182.24). When the lateral crura are of an appropriate length but lack the stiffness for appropriate lateral wall support, lateral crura strut grafts are a good option. Lateral crura strut grafts are usually created from stiffer cartilage from the septum or rib. Their length depends on the needs of the graft. Longer grafts are used when lateral wall collapse is a problem or when correcting alar retraction. These grafts are typically 20 to 30 mm in length, 3 to 4 mm wide, and 1 to 2 mm thick. Local anesthetic should be injected to hydrodissect the plane beneath the lateral crus. Several minutes after injection, a pocket can be dissected from the cephalic margin of the lateral crus between the cartilage and the vestibular skin. The graft is then placed in the pocket and affixed with several 5-0 PDS mattress sutures with the knots placed above the lateral crus. When reinforcing the lateral crura with lateral crural strut grafts, more of the lateral crura can be removed without compromising the support of the nose.

Often there is a lack of support lateral to the tip in the alar margin. This disruption of the favorable triangular shape of the base creates shadows that make the tip appear to be separate from the alae (Fig. 182.25). The cause of poor support in this area can be cephalic positioning of the lateral crura or prior tip modifications. Alar rim grafts can be used to correct this pinched look (9). These are narrow cartilage grafts that are usually 5 to 8 mm in length, 2 to 3 mm in width, and 1 to 2 mm thick. They are placed in pockets along the caudal aspect of the marginal incision (Fig. 182.26). Alar rim grafts should be softer than other grafts because they are susceptible to becoming visible medially if they extend into the tip. After placing the grafts in the pockets, they are fixed with 6-0 Monocryl suture at the medial aspect. The area medial to the suture should be gently morselized with a Brown-Adson forceps to further minimize the likelihood of graft visibility. Grafts that are too stiff also tend to be visible and sometimes palpable. Alar rim grafts are also an effective way to correct external valve collapse. However, it is important to realize that alar rim grafts can cause alar flare and increase the size of the nostril. As a consequence there is an increased need for alar base reduction in patients with alar rim grafts (4).

Patients who have malpositioning of the lateral crura require a completely different approach to changing the nasal tip contour. To address the "parentheses" appearance on frontal view from bulbous cephalically positioned crura, one can perform a cephalic trim and place dome sutures with or without lateral crural strut grafts. If the lateral crura are not sufficiently flattened, then the lateral crura can be repositioned caudally. To accomplish this cephalic trim is performed followed by dissection of the

Figure 182.24 Bulbous tip **(A,B,C)** before lateral crural strut grafts and **(D,E,F)** after procedure.

lateral crura from the vestibular skin, suture lateral crural grafts to the undersurfaces of the lateral crura, and then reposition the lateral crura into caudally positioned pockets (1). This eliminates the supratip fullness and decreases fullness in the supra-alar region while increasing support along the alar margin. It also places supportive cartilage along the sidewall of the nose and prevents lateral wall collapse (1).

To provide additional tip projection and definition, tip onlay grafts can be used. These are soft cartilage grafts trimmed into a rectangular or elliptical shape to simulate the ideal tip highlight and are sutured over the domes in a horizontal orientation. It is important to gently crush the cartilage to prevent the graft from becoming visible postoperatively (4).

In some patients with weak or diminutive lower lateral cartilages that will not achieve the desired tip projection with sutures and onlay grafts, shield grafts can be used (1). Shield grafts are primarily used in secondary rhinoplasty, augmentation rhinoplasty, or in primary rhinoplasty patients who have an underprojected tip with thick skin and a deficient tip lobule (1). A shield graft is attached to the medial crura in the infratip lobule (Fig. 182.27). The posterior edge should have a shallow bevel to allow

Figure 182.25 Example of alar rim and supra-alar pinching as a result of weakening the nose.

the contour of the graft to blend with the caudal edge of the medial crura. Because the purpose of the graft is to push into the tip skin to increase projection, no matter how much the anterior edge is beveled, a risk exists of the graft being visible after surgery. Because of this, the authors avoid using shield grafts in thin-skinned patients (10). Although thick-skinned patients are tolerant of shield grafts, medium-skinned patients should have some sort of camouflage of the leading edge. Perichondrium and fascia are excellent materials for softening the contours of a shield graft. Several layers can be used to prevent visibility of the graft in the long term. A buttress or cap graft is another method for camouflaging a shield graft (5,10).

Figure 182.27 Shield graft affixed to the medial crura.

This graft is a small rectangle of cartilage that is sutured to the cephalic edge of the shield graft and stabilizes it while providing a smoother transition between the shield and the domes.

Sometimes the lateral crura are so misshapen or overresected that lateral crural grafts are appropriate for reconstruction (5,10). Lateral crural grafts are also a good way to camouflage a shield graft that projects more than 3 mm above the domes, whether or not the lateral crura need structural reinforcement. These grafts create a transitional structure that bridges a shield graft to the lateral crura and simultaneously provides lateral support to the tip (Fig. 182.28). Lateral crural grafts are sutured to the anterolateral margin of a shield graft with a 6-0 Monocryl suture. A 6-0 Monocryl suture is placed laterally to secure the lateral crural graft to the existing lateral crus.

The importance of tip cartilage camouflage cannot be overemphasized. Although postoperative edema can be present for years after surgery, the surgeon should anticipate that eventually the edema will resolve and potentially reveal the underlying structure of the tip.

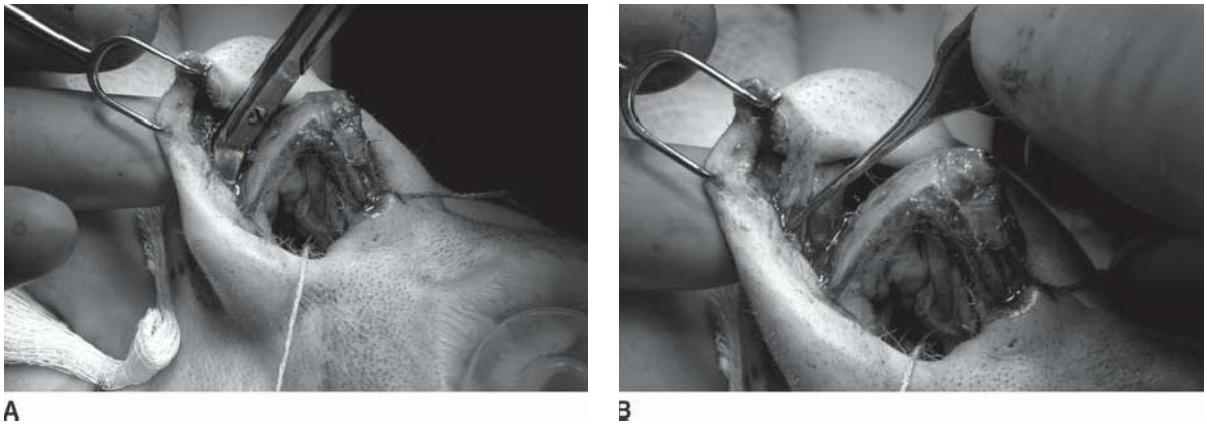

Figure 182.26 Proper insertion of alar rim grafts.

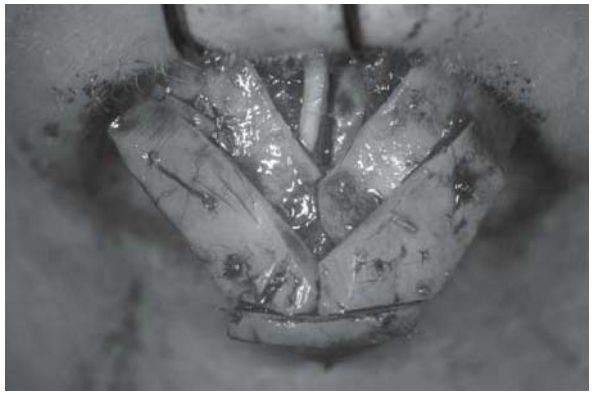

Figure 182.28 Lateral crural grafts conjoined with a shield graft.

Perichondrium from an auricular or costal cartilage graft is an excellent material for covering tip grafts (Fig. 182.29). Patients should be warned that the use of perichondrium will result in prolonged postoperative edema in the tip. In thin-skinned patients, this is favorable and should be described to patients as such. Once the postoperative edema resolves, the tip will have a soft, natural contour.

Surgery of the nasal tip is a challenging endeavor and fraught with pitfalls. Mastery of surgical technique must be paired with a clear understanding of the three-dimensional topography of the natural-appearing nasal tip. The goal should be to preserve the horizontally oriented tip highlight that transitions from tip lobule to alar lobule. This result is best accomplished by stabilizing the base of the nose, conservatively suturing the tip, and applying appropriate grafting techniques (1). These techniques will enable the surgeon to have more predictable long-term results and achieve a more natural postoperative outcome.

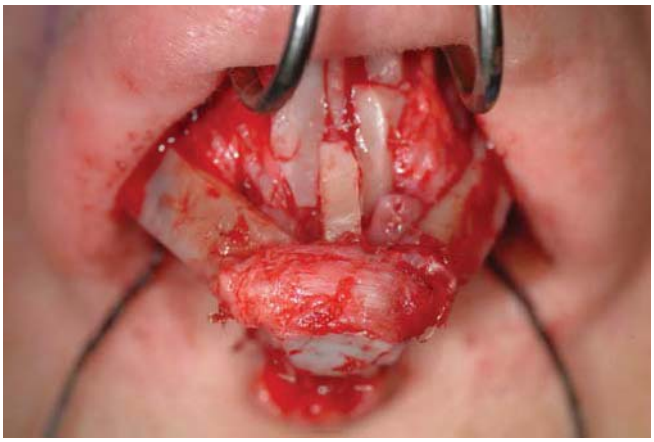

Figure 182.29 Perichondrium covering nasal tip grafts to prevent postoperative graft visibility.

HIGHLIGHTS

- The focus of nasal tip contouring should be more on creating favorable shadows and highlights and less on narrowing.
- Removal of structurally supportive tissue weakens the nose.
- Thick-skinned patients often need their tip structures projected into the skin–soft tissue envelope.
- Thin-skinned patients benefit from preservation of dome continuity and need extensive soft tissue camouflage of any cartilage grafts to prevent them from becoming visible.
- The tripod model provides the basis for understanding changes in rotation and projection.
- Before making any meaningful changes to the tip, first stabilize the nasal base.
- Vertical contributions to tip bulbosity can be addressed with a conservative cephalic trim of the lateral crura.
- Horizontal contributions to tip bulbosity can be corrected with two separate dome-binding sutures.
- Perichondrium and fascia are valuable materials for tip graft camouflage.
- Patients must understand that their noses will change over many years as the forces of scar contracture act on the supportive structures.

Management of the Crooked Nose

183

Craig S. Murakami *Richard A. Zoumalan*

The treatment of a crooked nose remains one of the most challenging problems in rhinoplasty surgery. Inadequate treatment can cause a persistent cosmetic deformity as well as problems with nasal obstruction. There are many techniques currently available for correction of the crooked nasal deformity. Regardless of the method used, revision rates remain significantly high. Patients differ in their goals for surgery, and it is essential that the surgeon understand their needs. While some patients are focused on the aesthetic outcome, others are more concerned with functional improvement. More commonly, patients have a combination of cosmetic and functional concerns.

ETIOLOGY

The crooked nose can be due to congenital, traumatic, or iatrogenic etiologies. A congenitally crooked nose is often associated with overall facial asymmetry. Sometimes the asymmetry is associated with a known syndrome. However, most patients have mild asymmetry that is nonsyndromic. The patient should be informed about these facial asymmetries preoperatively and made aware of how this may or may not affect their outcome. Treatment of the congenitally crooked nose can be difficult since the surrounding deviation of the internal and external facial framework makes it difficult to find a common midline.

Traumatic crooked noses can be the result of a low velocity force that causes a simple unilateral infracturing of the affected nasal wall or a higher velocity force that causes bilateral nasal wall deviations along with deviation of the septum. Severe nasal injuries may also be associated with deformities of the orbits or maxilla.

Iatrogenic crooked nasal deformities caused by previous surgery may be the result of poorly executed osteotomies, excessive resection of bone or cartilage, and/or poor wound healing. The nose can sometimes heal in unpredictable ways due to the effects of soft tissue contracture, cartilage memory, severe bone and cartilage asymmetries, aging, glasses, gravity, and so on.

A severely deviated nose almost always has a major septal deformity. Treating the deviated internal septum is usually necessary to facilitate correction of the deviated external nasal component (1–3). The nasal septum has a syndesmosis between the quadrangular cartilage and bones of the vomer and ethmoid that is unique in the human body. Cartilage growth occurs in the perichondrium of the anterior bony septum without eventual ossification (4). Disruption of this process *in utero* or during childhood can result in the loss of vertical growth. This disruption also has implications in pediatric nasal surgery, as violation of the posterior septum at this junction and the bony septum can have deleterious impact on the growth center of the septum.

HISTORY AND PHYSICAL

Making an accurate diagnosis is central to the management of the crooked nose, as there are many potential configurations of crooked noses. The surgeon must begin with a detailed history and physical examination, paying careful attention to all aspects of the nose. The history should include information regarding the patient's medical conditions, previous nasal surgery, nasal trauma, nasal airway, allergies, and drug and tobacco use. The mechanism of injury may be helpful to know, as it will help to separate the traumatic deviations from the congenital ones. If a patient had previous surgery, it is sometimes helpful to obtain previous operative report and radiographic studies.

To begin the examination, the surgeon should first establish the midline of the face as defined by a vertical line through the menton, the upper incisors, the philtrum, and the glabella. Figure 183.1 shows how a vertical line drawn through from the glabella, through the philtrum, and through the menton can give the doctor a sense of whether the nose is crooked. It can also help identify asymmetries

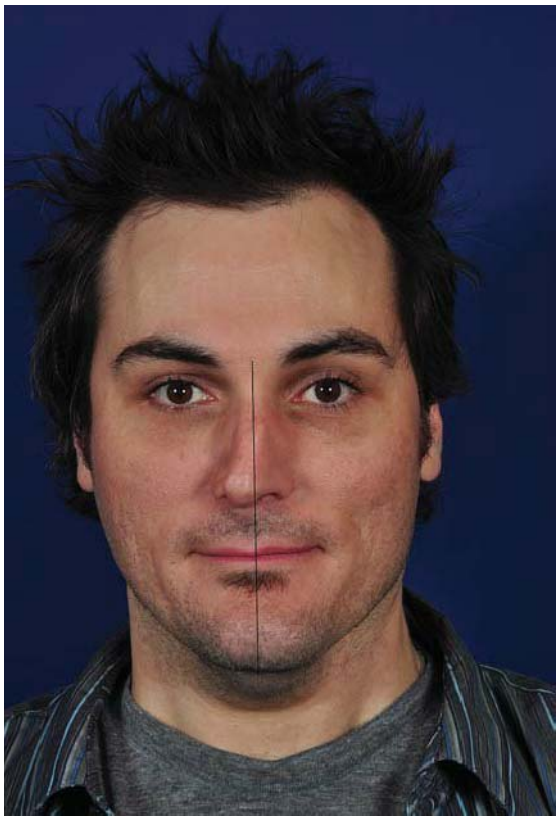

Figure 183.1 A *vertical line* is drawn from the glabella, through the philtrum, and then through the menton. This line can help identify asymmetries and deviations. One can see that the deviation of the nose lies in the middle and lower third of the nose. In this patient, the vertical lines allow the viewer to see asymmetry of the mandible and midface. His left side is stronger and has more volume than his right side.

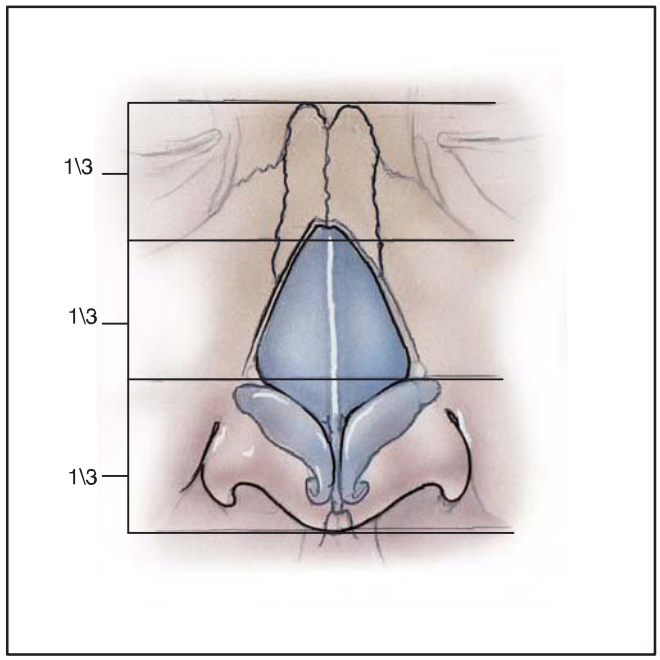

Figure 183.2 The nose can be divided into thirds. This is central to diagnosis and treatment of a crooked nose. The components of the thirds can be seen in this illustration.

of the face that were previously unrecognized. The nose is then divided into thirds, that is, the upper, middle, and lower thirds (see Fig. 183.2). For the most part, we can generally say that the upper third is composed of the nasal bones, the middle third is composed of the septum and upper lateral cartilages, and the lower third is the septal angle and lower lateral cartilages. Each third is individually examined in relation to the midline or relative midline. The thirds are classified into right, left, or center of midline. Given the number of possibilities, there are theoretically 26 permutations of crooked noses. The 27th possibility is a center–center–center nose, which is a straight nose. Half of these permutations are mirror images of each other. Figure 183.3 demonstrates five of these permutations (5).

The surgeon should palpate the nose carefully to feel the thickness of the skin and the position of the bones and cartilage and determine tip strength. Convexities, concavities, and buckles in the cartilage can also be determined using palpation. Tip support is determined by manually compressing the tip. Additionally, the surgeon should feel the caudal septum and the septal angle to assess its strength and integrity, as well as the position of the septum in relation to the midline.

A thorough endonasal exam should be completed in a systematic manner to determine the position, health, and function of the nasal septum, turbinates, the internal and external nasal valves, and nasal mucosa. The patient should be observed while taking normal and accentuated breaths through the nasal airway. The examiner will often see external evidence of nasal valve collapse, and

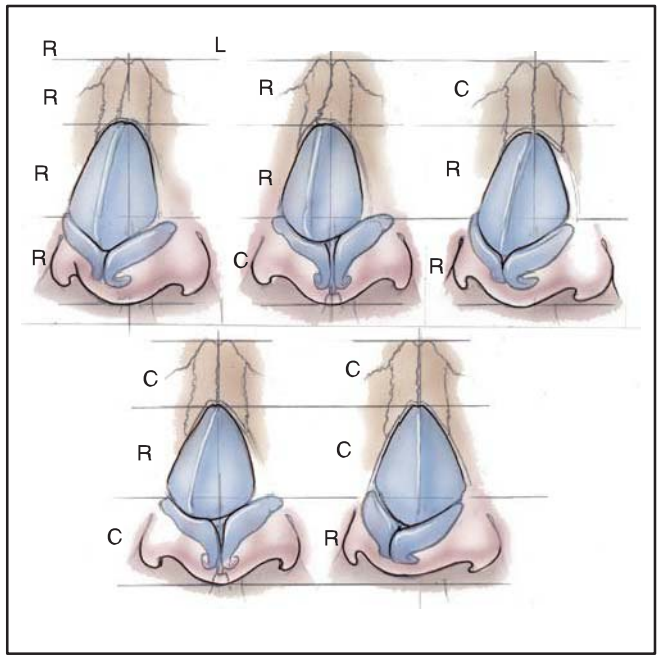

Figure 183.3 Artist-rendered images of five different permutations of crooked noses. There are 26 possible configurations.

the area of collapse should be noted. The nasal mucosa should be initially examined without decongestion. This helps assess whether there is an allergic or reactive component. Finally, the nasal mucosa must be decongested with either oxymetazoline or 0.25% Neo-Synephrine. The decongestion may reveal posterior and high dorsal septal deflections that may have been previously hidden by inflamed mucosa. If there is history of previous surgery or trauma, the septum should be palpated with a cotton tip applicator or cerumen loop to determine if the septal cartilage is missing or deficient. In a severely deviated nose, the full extent of the septum may not be able to be visualized without a fiberoptic device. The size of the turbinates must also be analyzed, as many patients can benefit from concomitant turbinoplasty. If the patient has a history that suggests chronic sinusitis, a CT scan may be of benefit.

A careful examination of the integrity of the internal and external nasal valve should be performed. When a patient inspires deeply, a weak internal valve can be seen externally by a depression just above the nasal ala or along the piriform aperture. The external valve is composed of the lateral crura, the suspensory ligaments of the lateral crura, and the fibromuscular tissue of the ala. Manually retracting the cheek laterally (the Cottle maneuver) can help assess if there is an element of valve insufficiency. This can also be done using a curette to stent open the internal and external nasal valves to independently determine where the weakness lies.

Radiographic assessment is necessary if a patient has signs and symptoms consistent with paranasal sinus disease or has polyposis. They may be also helpful in patients who previously sustained major trauma that required open reduction and internal fixation of the craniofacial skeleton. This surgical hardware will need to be identified prior to surgery, as it may need to be removed before osteotomies can be performed.

Standard rhinoplasty photographs must be taken for medical documentation and to assist with the evaluation and analysis of the patient. These views include the frontal, profile, three-quarter, and base views. The authors also like to take two additional photographs when patients have crooked noses. One is the bird's-eye view, which gives the surgeon more information on the shape of the dorsal line (see Fig. 183.4). The use of overhead flash is preferable as it most closely duplicates overhead sunlight, which accentuates deviations. The other is the three-quarter base view where the entire dorsum and nasal walls are visible in relationship to the nasal base (see Fig. 183.5). Photos must be available and easily visible in the operating room during surgery. Due to local anesthetic injections and surgical edema, asymmetries can become masked or imperceptible. Therefore, the surgeon must periodically refer to these photos during the operation. Postoperative photos are usually taken at 6-month and 1-year intervals to track healing progression.

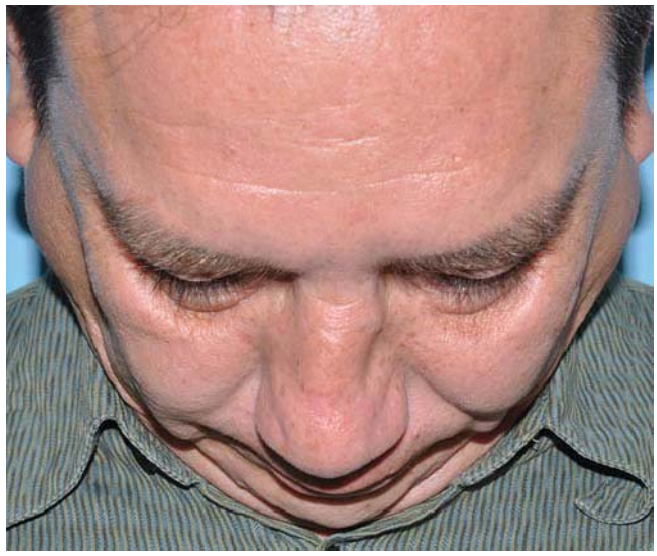

Figure 183.4 This is an example of a bird's-eye view. This allows one to see another perspective of the dorsal line.

TREATMENT STRATEGY

Surgical correction of the deviated nose can be conceptually and strategically divided into the upper third, middle third, and lower third. The upper third is composed of the nasal bones and the frontal process of the maxilla. The middle third is composed of the bony cartilaginous junction (called the keystone), the upper lateral cartilages, and the dorsal septum. The lower third is composed of the caudal septum and the lower lateral cartilages.

Septum

Septoplasty surgery in the crooked nose can be approached through a hemitransfixion incision. This incision allows easy access to both sides of the septum and facilitates easy repositioning of the caudal septum to the facial midline. To best mobilize the septum, separation of the posterior and

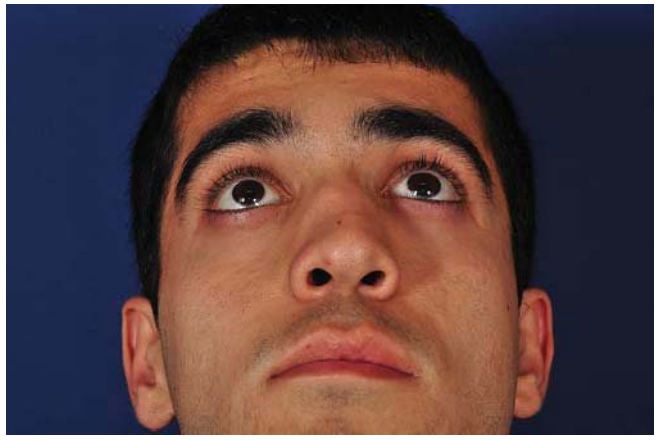

Figure 183.5 This is an example of the three-quarter base view. This view gives a view of the dorsal deviation with relation to the tip.

inferior osseocartilaginous junction plus elevation of the mucoperiosteum of the maxillary crest is often required. Releasing the attachment of the upper lateral cartilages can also help mobilize a septum that is deviated.

A dorsal and caudal "L"-shaped strut must be maintained at least 10 mm in width. The dorsal strut must maintain stable fixation at the superior bony–cartilaginous junction (the key area of the dorsum) to prevent saddling of the middle nasal vault. The caudal septum should also have support from the nasal spine and maxillary crest. Deviated cartilage is either removed or recontoured by scoring the concave side of the deviation with a scalpel. These partial thickness cuts can weaken the septum in a manner that facilitates repositioning toward the midline. Spreader grafts can also help correct deviations of the dorsal septum (see section on correction of middle third). Caudal deviations can be corrected with vertical scoring on the concave side of the septum. Retrograde soft tissue dissection behind the medial crura must be done to create a central pocket in the membranous septum. With severe deviations of the caudal septum, the mucosa is scarred toward the side of the caudal deflection. If a pocket is not made for the newly straightened caudal septum, the contracted mucosa will push the septum back toward the side of the deviation and cause a relapse of the nasal obstruction.

If the septal deviation is severe and the surgeon is unable to correct it through the endonasal or external approach without significantly compromising support to the dorsal or caudal strut, an extracorporeal septoplasty should be performed. In this procedure, the cartilaginous septum is removed, straightened, contoured, and then reimplanted (6). It is important to leave a small portion of the dorsal cartilage in the keystone area (area where the septum articulates with the nasal bones) to provide a point of suture fixation to prevent postoperative collapse of the dorsal septum. The use of a polydioxanone sheet to stabilize the cartilage grafts has been reported to facilitate the extracorporeal technique (7).

If turbinate hypertrophy is present and causing obstruction of nasal airflow, a submucous resection is performed.

Upper Third

Asymmetry of the upper third of the nose is caused by deviation of the upper bony nasal framework. The nasal bones articulate with the frontal bones superiorly and the ascending process of the maxilla laterally. They are thickest at the nasion superiorly and taper to become thinner as they approach the caudal articulations with the upper lateral cartilages. Asymmetry of the upper bony nasal dorsum is often associated with high deviations of the septum. While small deviations can be amenable to rasp reduction or small onlay grafts, osteotomies are typically needed to correct most deviations of the upper third (8). The three primary goals of osteotomies are to straighten a deviated nasal dorsum, narrow the nasal sidewalls, and close or open the nasal vault (9). It is important for the surgeon to know which of these goals are necessary in any given situation. There are many ways to perform osteotomies. See Figure 183.6 for three different patterns of osteotomies. If the roof is open from trauma or dorsal reduction, medial osteotomies may not be necessary (9). Lateral osteotomies are usually performed in a high–low–high fashion. However, a high deviation may require a high–low–low configuration to center the upper third. If the nasal bones are mobilized, but the upper third remains crooked, this may be due to a persistently deviated bony dorsal septum that extends into the superior septum (10). Two approaches can be taken to center the deviated superior septum. The first option is to mobilize the superior aspect of the septum with percutaneous medial osteotomies using a 2-mm chisel, taking care not to extend the fracture into the cribriform plate. The medial osteotomy can also be done as a "cross-root" osteotomy. In this technique, the osteotome is used to cut across the bony septum and the upper nasal dorsum using an endonasal approach. A curved osteotome is placed medially on the convex side of the nose at the site of a typical medial osteotomy. The curved osteotome cuts across the nasal root to the contralateral side to mobilize the central portion of the upper third. With either the percutaneous transverse or the cross-root osteotomy, the entire upper third should be easily mobilized from side to side once the lateral osteotomies have been completed.

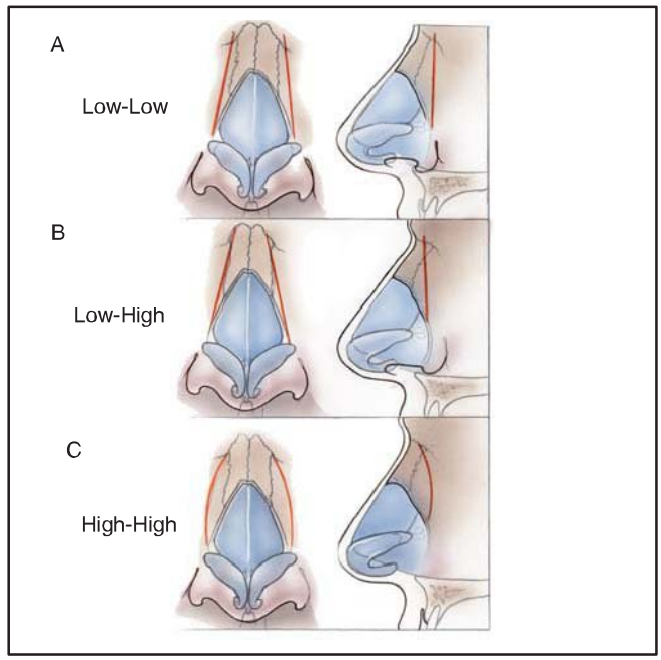

Figure 183.6 This figure shows three different types of osteotomies that can be performed. The upper image is that of a low–low osteotomies, where the osteotomy is closer to the maxilla (low) throughout its route. The middle image is that of an osteotomy that starts low and ends high (closer to the dorsum). The bottom image is that of a high–low–high route, which is the most commonly used type of osteotomy route. The midportion of the osteotomy dips closer to the maxilla (low).

Preserving the lateral nasal periosteum and the underlying mucosa as much as possible will avoid excessive medial or posterior displacement of the nasal walls after osteotomies are completed. This is accomplished by using small osteotomes and elevating a small tunnel of periosteum along the lateral osteotomy site prior to creation of the osteotomy.

Another option for the crooked upper nasal third is to camouflage the deviation with bony reduction on the convex side and onlay cartilage grafting on the concave side. This reduction and contralateral augmentation of the upper nasal third will help center the upper third without aggressive osteotomies. This technique works well for minor deviations when the bone is relatively thick.

Middle Third

The middle third of the nose is composed primarily of the paired upper lateral cartilages and the dorsal nasal septum. Inferiorly, the upper lateral cartilages articulate with the lower lateral cartilages via the scroll. Superiorly, both the upper lateral cartilages and the septum articulate with the nasal bones. Standard septoplasty techniques emphasize correcting deviations along the inferior aspect of the septum. Deviations along the dorsum may require separating the upper lateral cartilage from the dorsal septum, vertical scoring of the dorsal cartilage, and osteotomy techniques. However, this at times may not correct the deviation sufficiently, and other methods must be used. Two commonly used methods are the spreader graft and the onlay camouflage graft (11). The spreader graft is a cartilage graft that is placed between the upper lateral cartilage and the septum. Figure 183.7 shows bilateral spreader grafts placed to help strengthen a deviated middle third. In order to place the graft, the upper lateral cartilage must be separated from the nasal septum. The mucosa is elevated from the dorsal septum, and the spreader graft is placed between the upper lateral cartilage and septum, and it is sutured into position. Unilateral or bilateral spreader grafts can be used for this purpose. The two spreader grafts may be of unequal thickness to correct for deviations of the nasal dorsum. In Figure 183.7, bilateral spreader grafts were placed. Another option is to use the medial margin of the upper lateral cartilage as an auto-spreader graft if there is redundant cartilage after straightening the dorsum. A vertical cut is made through the redundant upper lateral cartilage 2 to 3 mm from the medial margin (preserving the mucosa) and turned inward as an auto-spreader graft (12,13). Using the redundant upper lateral cartilage saves precious septal grafting material for other parts of the nose. For noses that require dorsal augmentation and widening of the middle nasal vault, an onlay spreader graft can be used (Figs. 183.8 to 183.10). The onlay spreader is a trapezoid-shaped graft that is placed over the dorsal septum and between the upper lateral cartilages (14). The graft is 4 mm wide superiorly, 5 to 6 mm wide inferiorly, and approximately 2 cm in length and running the length of the dorsal septum.

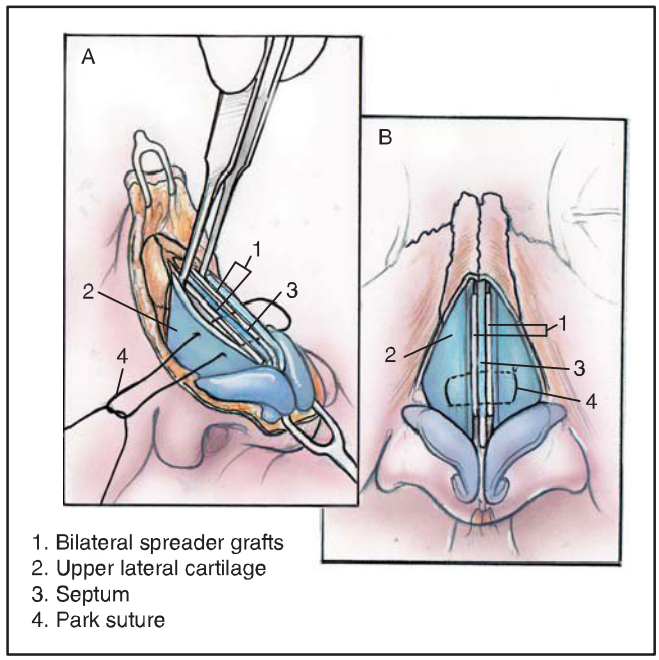

Figure 183.7 This illustration demonstrates how bilateral spreader grafts are placed. Cartilage is placed from the edge of the nasal bone and along side the septum, on each side. At least one mattress suture is placed to maintain the position of the spreader grafts in open external rhinoplasty. In endonasal rhinoplasty, suture fixation may not be necessary if properly sized pockets for the grafts are created.

It is important to avoid excising upper lateral cartilage until absolutely necessary. If the upper lateral cartilages are cut before the deviation is fixed, there may be a lack of upper lateral cartilage on the side of the deviation once the nose is shifted to the midline.

Deviations of the middle third of the nose can also be due to dislocation of the upper lateral cartilages from the caudal margin of the nasal bones. The surgeon can sometimes reapproximate the cartilages back to their anatomic position and suture-fixate them to the periosteum; otherwise, camouflage grafts can be utilized. Deviations can also be caused by depressions due to a collapse of an osteotomized or traumatically fractured lateral nasal wall. These deviations can be corrected with onlay grafts placed over the lateral nasal wall or spreader grafts. The decision to use an onlay graft versus a spreader graft is based on the patient's nasal airway, the size of the depression, and the shape of the upper lateral cartilage. If the size of the depression is small and is not affecting the internal nasal valve, a small onlay graft of crushed or precisely contoured septal cartilage suffices. If the depression is small and the nasal valves narrow, spreader grafts are preferred since they improve the airway as well as correct the depression. If the depression is large and the airway is narrow, a combination of both spreader grafts and onlay grafts over the upper lateral cartilage, dorsum, or the cephalic margin of the lower lateral cartilage may be necessary (Figs. 183.11 and 183.12).

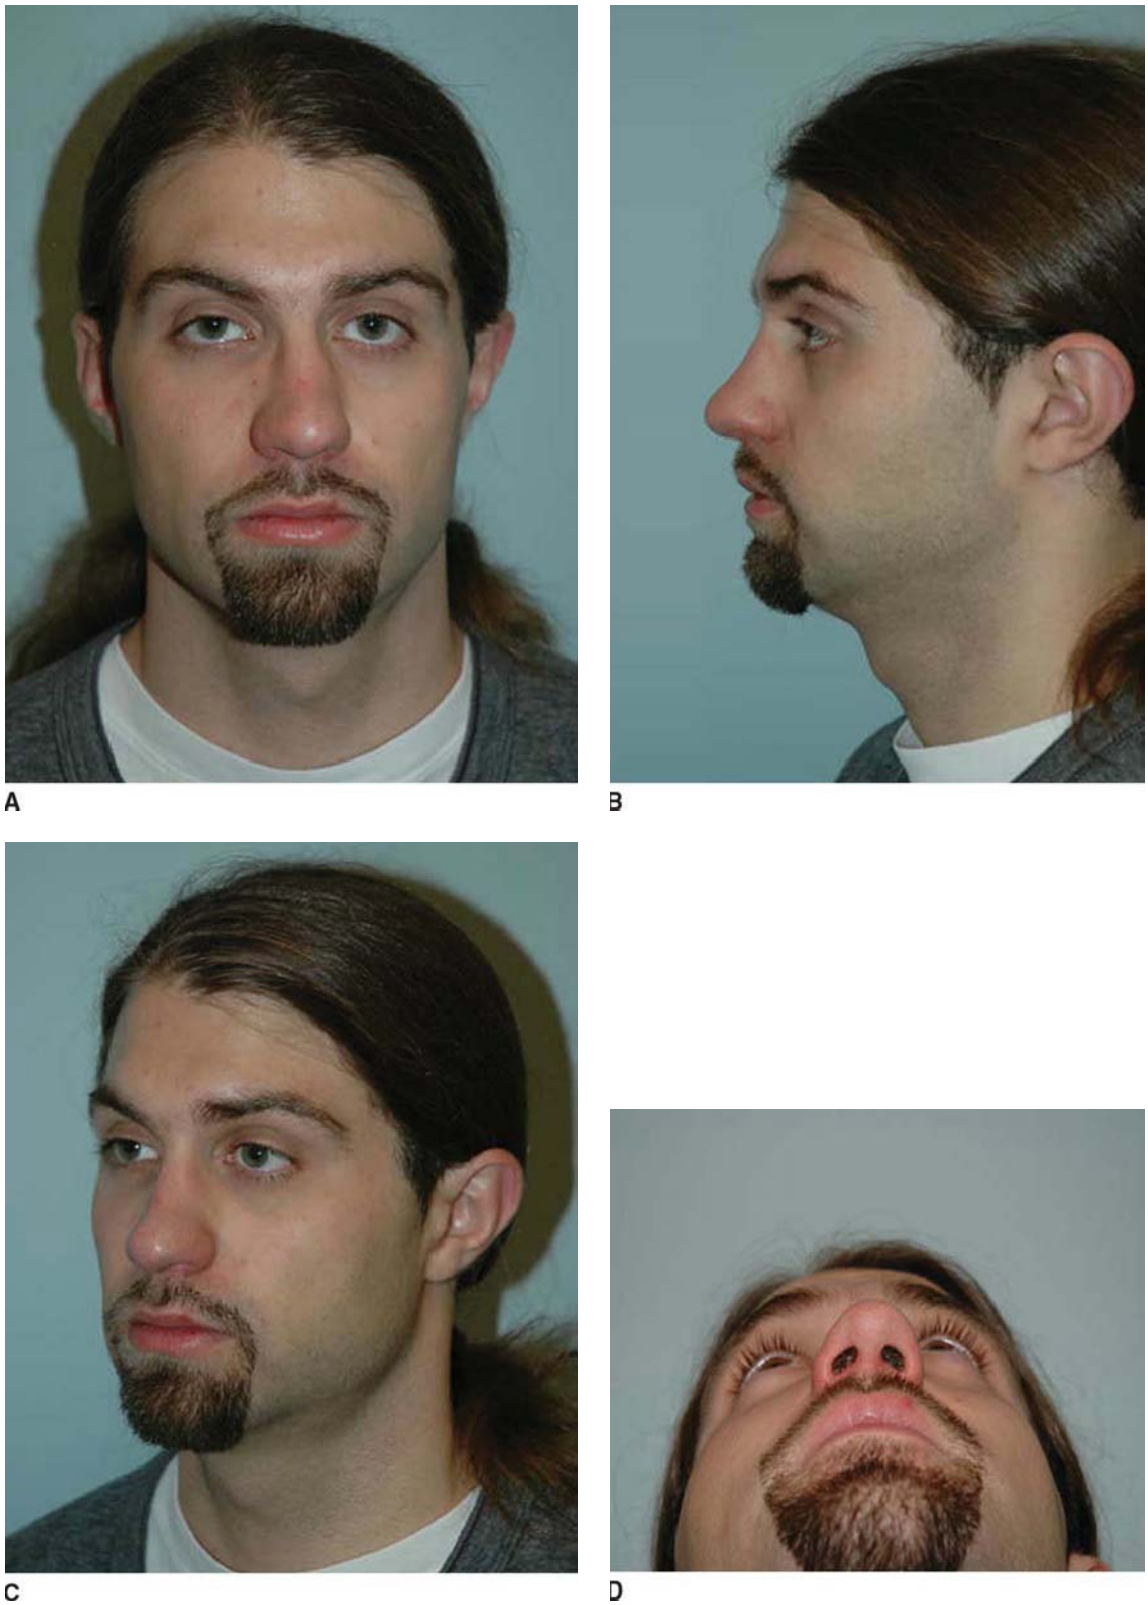

Figure 183.8 Case One. This is a 25-year-old male with a posttraumatic nasal deformity. He has a history of a prior reduction of a nasal septal fracture. He complains of persistent nasal obstruction and nasal deformity obscured by thick skin. Preoperative **(A–D,I)** and postoperative **(E–H,J)** photos can be seen here.

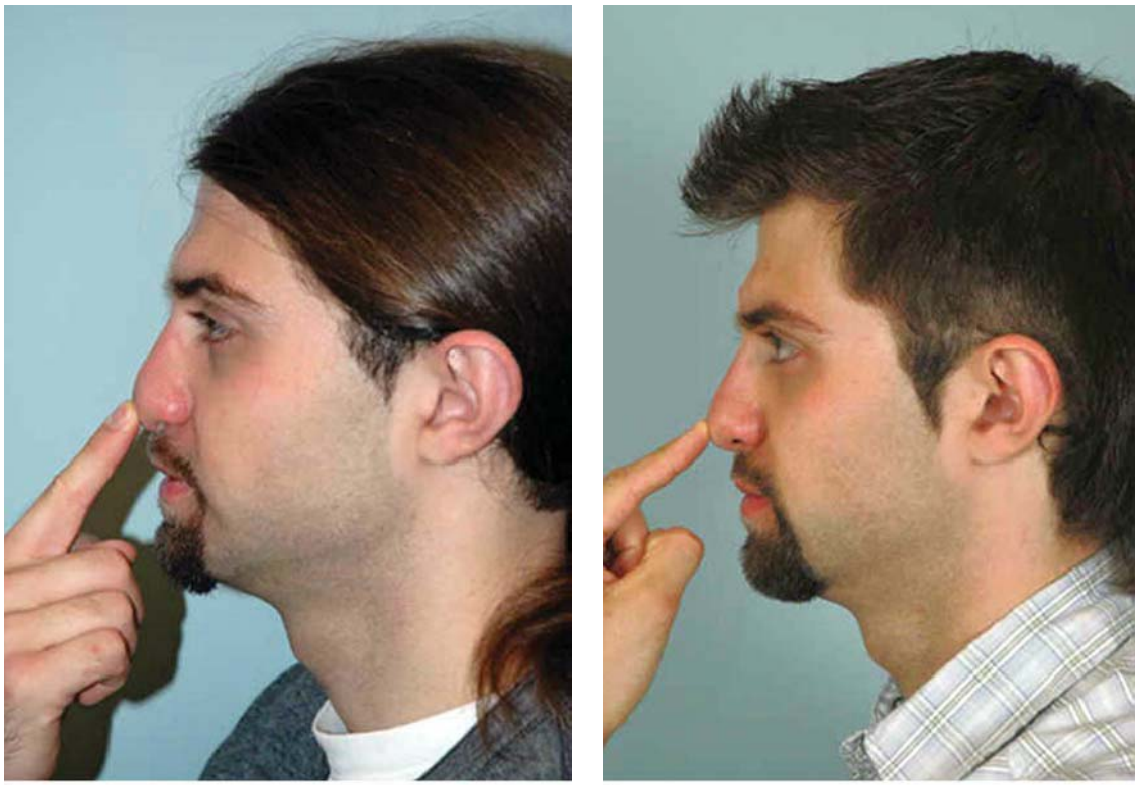
Figure 183.8 *(Continued)*



I J

Figure 183.8 *(Continued)*

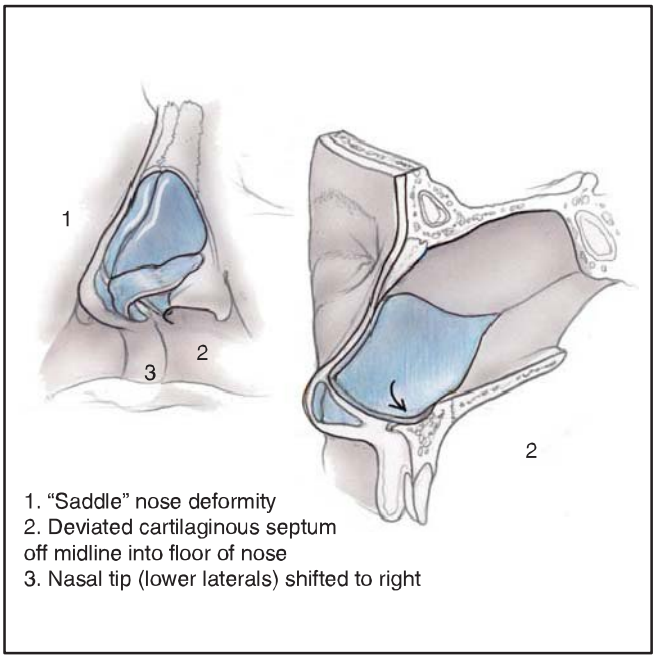


Figure 183.9 The patient in Case One has a saddle deformity that is a depression of the middle third. The septum is depressed into the left nasal cavity, which causes deviation of the middle third. The lower lateral cartilages are not in contact with the septum because the tip is deviated to the right. Disarticulating the septum from the maxillary crest allows the surgeon to rotate the septum upward to increase dorsal height. This acts to reduce the saddle depression and also places the septum between the medial crura of the lower lateral cartilages. This all helps straighten the middle and lower thirds.

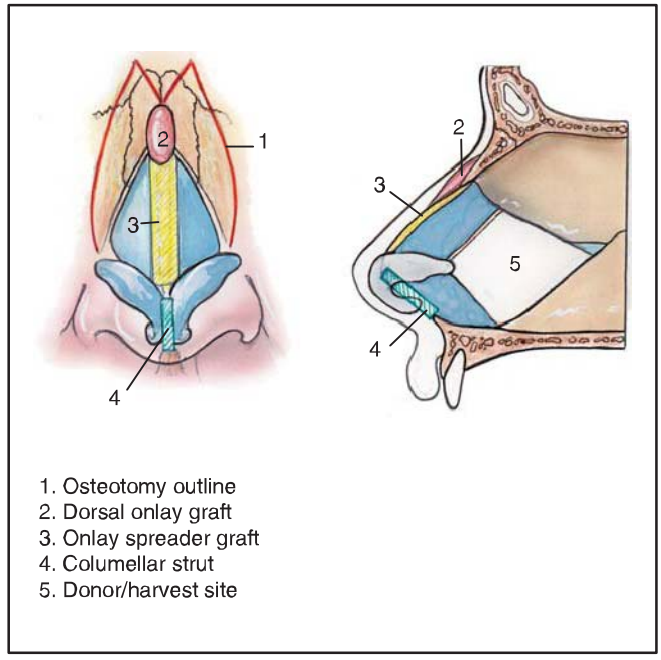

Figure 183.10 To create a nasal structure that maintains a straighter shape, the patient in Case One underwent open (external) septorhinoplasty. Autologous septal cartilage was used. The upper third was straightened with bilateral medial and bilateral lateral osteotomies. To straighten the middle third, he underwent the septal procedure described in this figure along with onlay spreader and dorsal onlay graft. The onlay spreader graft provides more dorsal augmentation to improve the saddle deformity. It also creates a higher support for the upper lateral cartilages and opens (increases) the internal nasal valve angle for better long-term breathing. The dorsal onlay graft was used for augmentation to create a uniform dorsum. To straighten the lower third, in addition to the septal procedure, a columellar strut helps keep the tip straight and supports the tip.

Figure 183.11 Case Two. This is a 30-year-old female patient who had childhood nasal trauma. She had a prior septorhinoplasty. She presented with a deviated nasal tip, twisted dorsum, severe caudal septal deflection to the left, concave left upper lateral cartilage, convex right upper lateral cartilage, and a buckled left lower lateral cartilage. Preoperative **(A–D)** and postoperative **(E–H)** photos can be seen here.

H

Figure 183.11 *(Continued)*

For onlay grafts, the ideal material is carved septal cartilage, followed by crushed septal or auricular cartilage, and then costal cartilage. Crushing must be kept to a minimum. The cartilage is crushed just enough to create a soft pliable layer that can be draped over the area of deficiency. It is best to place such grafts at the end of the case when the incisions are nearly closed so that the grafts do not get displaced. If necessary, the grafts can be sutured into position with either a fine monofilament absorbable or permanent suture.

Lower Third

Anatomically, the lower third of the nose consists of the paired lower lateral cartilages, the caudal nasal septum, and the nasal spine. Careful inspection and palpation can help the surgeon mentally "deglove" the nose to visualize a three-dimensional virtual image of the structures below. Palpation of the septum in relation to the maxillary spine can help determine whether the septum is dislocated from the midline. Deviations of the lower third are often due to deflections of the caudal septum or deviation of the lower lateral cartilage. However, at times, the lower lateral cartilages are asymmetrically malformed causing deviation of the nasal tip. Asymmetry of the lower lateral cartilage can be due to congenital variation, aggressive iatrogenic resection, or traumatic alterations. The two lower lateral cartilages may have significant differences in shape and size. Correction of the lower lateral cartilages to achieve symmetry can be performed with a number of methods. Many surgeons prefer the external approach for severe lower third asymmetries since the asymmetries are easier to visualize *in vitro*. Endonasal approaches can equally address the issue found in the crooked nasal deformity. Ultimately, the choice of approach depends on each surgeon's comfort and experience. The surgeon must decide whether a surgical attempt at repositioning or modifying the lower lateral cartilages back to a symmetric tripod is possible, or if it is better to use camouflage augmentation or reduction techniques to create tip symmetry.

Lower lateral cartilages that are severely distorted and asymmetric should be mobilized by releasing scar tissue and the vestibular mucosa. Some grafts such as the columellar strut and alar batten grafts (or lateral crural strut grafts) provide structural support. Once the structural integrity is returned, onlay grafts of crushed or carved cartilage can be used to improve symmetry. Suture shaping techniques, whereby a surgeon shapes the cartilages using mattress sutures, is a safe and effective way to shape the lower lateral cartilages without the risk of irrevocably damaging the cartilages if the attempt fails (15). For this reason, suture techniques have become very common. When the nasal tip is severely deviated, one often finds marked asymmetry between the two lower lateral cartilages, especially when the asymmetry is congenital or long-standing. The longer medial or lateral crura may require shortening or the shorter sides lengthening. The surgeon must balance these decisions based on the status of tip projection and rotation (Fig. 183.12). Dividing the longer crura and suturing the overlapping segments at a length symmetrical with the contralateral lower lateral cartilage will shorten and stabilize the longer crura. The authors prefer 6-0 polypropylene suture for this purpose since they are permanent and nonreactive.

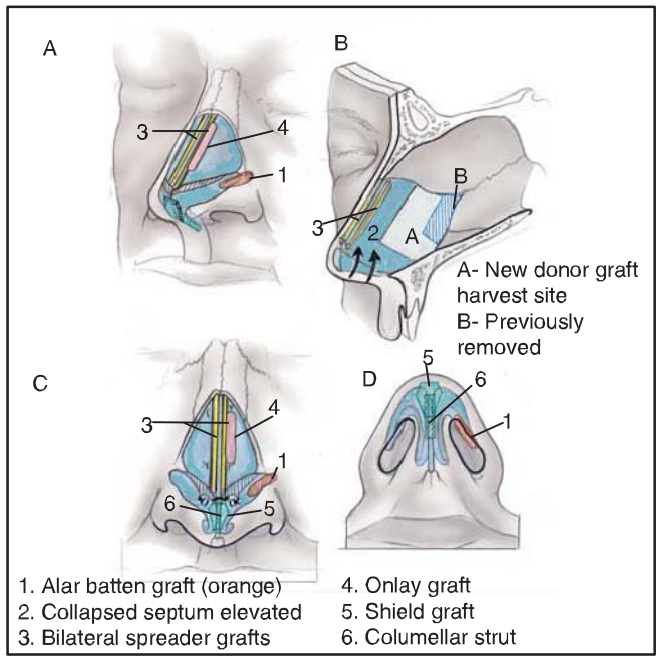

Figure 183.12 The patient in Case Two underwent revision open (external) rhinoplasty. Autologous septal cartilage was used, along with ear conchal cartilage graft. The upper third was straightened using bilateral medial and bilateral low–high–low osteotomies. To straighten her middle third, bilateral spreader grafts were placed, along with a left dorsal onlay graft to account for the concavity of the upper lateral cartilage. Her collapsed septum was also elevated as in Case One (*black curved arrows*), but to a lesser degree. To straighten her lower third, a combination of suture techniques were used along with a left alar batten graft and columellar strut. Finally, a shield graft was placed for increased tip projection and definition.

FINISHING TOUCHES

After the nose is straightened, the surgeon should view the patient from the head of the bed to ensure the nose is at midline. This view helps pick out minor asymmetries along the entire length of the nose. Final camouflage grafts may be necessary using thin pieces of crushed or lightly scored cartilage. Septal splinting may be helpful in maintaining a straight septum and preventing blood or serum collections, which can result in areas with increased thickness. An external thermoplastic splint is applied to maintain the nose at midline. It cannot be used to straighten a nose that is crooked at the end of the operation. The tape and splint stay on for 6 to 7 days. Postoperative massage may be helpful. Patients are instructed to apply gentle pressure to the lateral nasal walls using the sides of the index finger while the palms of the hand are facing outward. This is done three to four times a day while facing a mirror during the second postoperative week. Patients are then seen by the surgeon at 1, 6, and 12 months during their postoperative recovery.

HIGHLIGHTS

- Successful management of the crooked nose requires a systemic approach that begins with a clear understanding of the patient's desires and symptoms.
- Any maneuver that improves a nose aesthetically may have implications in the functionality of the airway.
- Careful thought should be given to which maneuvers can correct the deformity without destabilizing the nose.
- There are two basic approaches toward dealing with a deviation: camouflage strategy and deconstructive/reconstructive. Camouflage is best for smaller asymmetries or depressions, and deconstructive/reconstructive strategy is best for more severe deviations. Either one or a combination of the two can be used to deal with a deviation.
- Conceptually dividing the nose into anatomic thirds simplifies and organizes a planned approach for each third with a strategy to correct it individually.
- After careful consideration to what is causing the deviation of the specific third, the forces that cause the deformity must be released. In posttraumatic or postsurgical cases, releasing scar tissue and the vestibular mucosa may be necessary to improve the asymmetry.
- After release and repositioning of the structures, the structures must be resutured in a way to construct a straight and stable framework.

Revision Rhinoplasty

184

Richard E. Davis

Cosmetic nasal surgery remains one of the most effective and long-lasting procedures in the cosmetic surgery arsenal. A successful rhinoplasty not only creates a more attractive nose, it diverts attention to the eyes, making for a more harmonious and thus a far more beautiful face. Yet, while cosmetic rhinoplasty ranks among the most commonly performed cosmetic operations, few if any surgeons ever fully master its numerous subtleties and peculiar nuances. Without question, the delicate and complex three-dimensional nature of nasal anatomy, the precise and unforgiving tolerances of the nasal airway, and the lofty expectations of the typical rhinoplasty consumer make cosmetic rhinoplasty an extremely challenging surgical procedure. Moreover, the profound psychological importance of the face makes rhinoplasty a tremendously high-stakes emotional endeavor in which even dramatic cosmetic improvements may sometimes fail to meet patient expectations. Nevertheless, despite the inherent technical challenges and emotional risks, the lure of a more attractive face is a powerful motivating force that is likely to ensure the popularity of cosmetic nasal surgery indefinitely.

Unfortunately, the growing popularity of cosmetic nasal surgery has also created a corresponding increase in the number of substandard rhinoplasty outcomes. While a failed rhinoplasty may occasionally result entirely from adverse tissue responses to a well-executed surgical procedure, failed surgeries are far more often the result of technical errors such as faulty cosmetic analysis, poor artistic judgment, overzealous tissue removal, and/or gross surgical ineptitude. And while *primary* (first-time) rhinoplasty is widely regarded as among the most challenging of all elective cosmetic procedures, treatment of a failed rhinoplasty, commonly known as *revision* (or *secondary*) rhinoplasty, is typically an order of magnitude more difficult. Unlike primary rhinoplasty in which the misshapen nose is devoid of surgical scarring, *every* revision rhinoplasty patient presents with previously operated tissues that have sustained varying degrees of skeletal disruption, subcutaneous fibrosis, circulatory impairment, and/or soft tissue contracture. Moreover, while the primary rhinoplasty patient is typically upbeat and excited about the prospect of a more attractive nose, the revision rhinoplasty patient is frequently burdened by apprehension, anxiety, and skepticism. Hence both the technical and psychological challenges of revision rhinoplasty are often formidable.

Without question, complex revision rhinoplasty ranks among the most technically demanding of all cosmetic surgeries and is best reserved for the revision rhinoplasty specialist. Indeed, even for the most gifted cosmetic surgeon, a near-singular devotion to nasal surgery is often necessary to develop proficiency in this extremely challenging surgical niche. And while the technical demands of revision rhinoplasty are considerable, exceptional technical skills alone are not sufficient for a successful practice. The truly effective revision surgeon must also possess a discerning, yet compassionate listening ear and a willingness to confront the myriad emotional issues that typically accompany a failed rhinoplasty. Often the patient's emotional trauma is considerable and may even lead to depression, social isolation, and impaired functioning. And since the emotional consequences of a failed rhinoplasty are often so profound, the importance of revision rhinoplasty cannot be overstated. Without question, complex revision rhinoplasty is an emotionally charged and technically demanding procedure that requires expertise, sensitivity, and exceptional technical skill.

Fortunately, contemporary techniques in revision rhinoplasty are now more effective than ever before. And while perfect restoration of the devastated nose is seldom possible, a carefully conceived and well-executed surgical treatment plan is often rewarded with considerable cosmetic and functional improvement. However, devising an effective surgical treatment plan is itself a complex and difficult undertaking. The surgeon must first correctly

assess the cosmetic deformity and the corresponding tissue characteristics, and then formulate a surgical game plan that will reliably achieve the desired cosmetic goal, all while limiting risk, cost, and treatment time. Once the game plan is formulated, the surgeon must also justify the treatment rationale and disclose potential surgical risks to an often apprehensive and nervous patient. Care must be taken not to trivialize the surgical risks and generate a false sense of security; yet at the same time, equal care must be taken to avoid overemphasizing the surgical risks and needlessly alarming the already worried patient. Fortunately, for the majority of patients a single operation in competent hands results in a satisfactory, albeit slightly imperfect restoration of nasal function and beauty. For those seeking maximum improvement, staged reconstruction often yields superior overall results when tissues permit, but few patients have the inclination, time, or financial resources to undertake sequential revision surgery.

For the surgeon, successful restoration of the devastated nose is more than a technical triumph; it is an immensely rewarding endeavor in which the emotional benefits to the patient can be truly life changing. Indeed, few other elective cosmetic procedures can impact a patient so profoundly, and the heartfelt appreciation of these individuals is extremely gratifying.

POSTSURGICAL DEFORMITIES OF THE NOSE

The severity of postsurgical nasal deformities varies widely, ranging from minor to irreversible. Patients presenting with gross overresection of the skeletal framework often constitute the greatest technical challenge, especially when coupled with fibrotic nasal skin, naturally weak nasal cartilage, and/or functional airway disturbances. And technical challenges are most severe when major anatomic deficiencies are coupled with genetically unfavorable wound-healing characteristics. Although some patients may present with only mild cosmetic or functional impairment, the *complex* revision rhinoplasty patient presents with moderate to severe cosmetic deformity, often complicated by concurrent nasal airway dysfunction. Sadly, a growing number of patients are presenting with profound cosmetic deformities following multiple misguided attempts at revision surgery. In many instances, tissue limitations, such as the cumulative effects of fibrosis, contracture, and vascular impairment, prevent successful surgical restoration of the nose, even in expert hands (Fig. 184.1). Although young healthy individuals can sometimes tolerate repeated nasal surgeries and still retain effective healing responses, revision rhinoplasty becomes progressively more difficult with each successive surgery, and all noses will eventually reach a point of surgical intolerance at some time. Determining whether or not a given nose can safely tolerate further surgery is a difficult and imprecise undertaking, and each patient must be approached cautiously in the context of potential surgical intolerance.

Figure 184.1 Severe nasal deformity presenting after multiple unsuccessful attempts at revision rhinoplasty.

In deciding whether or not to pursue further surgery, a thorough physical examination of the nose is paramount. Direct physical examination is the only available means of assessing the anatomic, structural, and physiologic severity of a failed rhinoplasty, and without this critical assessment, the likelihood of a successful revision surgery is greatly diminished. Adverse physical findings such as a severely collapsed nasal framework, scarred and inelastic nasal skin, signs of borderline tissue perfusion, or dense cicatricial stenoses of the vestibular skin are the hallmarks of pending surgical intolerance, and these findings should prompt a sober reassessment of the need for further surgical treatment. In the worst-case scenario, numerous adverse physical findings combine to yield a strongly unfavorable risk-to-benefit ratio and a relative contraindication to further cosmetic surgery. On the other hand, debilitating functional impairment such as severe obstructive sleep apnea resulting from profound nasal airway obstruction may justify further intervention despite the increased surgical risk. Ironically, some seemingly intolerant noses will respond surprisingly well to a properly executed revision rhinoplasty, while some seemingly healthy noses will occasionally suffer significant wound-healing complications. Hence, the decision to reoperate is a dilemma for which there is no easy answer, and since no patient is ever fully immune from unforeseen complications, the prudent surgeon must balance the potential surgical risks against the emotional and physical burden of an untreated nasal deformity.

Although there are an infinite number of postsurgical nasal deformities that may arise following primary cosmetic rhinoplasty, cosmetic deformities can be loosely categorized as those of skeletal tissue *excess* and those of skeletal tissue *deficiency*. Postsurgical contour deformities of skeletal tissue excess are most often the result of incomplete or neglected treatment of congenital skeletal

overgrowth such as a persistent dorsal hump or a persistent hanging columella. In straightforward cases of skeletal tissue excess, the prognosis is often highly favorable since revision surgery simply entails completing the primary rhinoplasty—the so-called completion rhinoplasty (see Case One).

Another common cause of skeletal tissue excess is the overzealous use of augmentation graft materials—the so-called overgrafted nose. Typically, surgical revision of the overgrafted nose is a difficult undertaking that requires reconfiguration of the nasal framework by removing, replacing, and/or modifying the existing structural elements to achieve an attractive, harmonious, and structurally sound skeletal framework. Treatment is particularly difficult when the existing nasal framework is twisted or asymmetric since extensive surgical "deconstruction"—and thus destabilization of the skeletal framework—is required. In contrast, revision of the overgrafted nose is comparatively straightforward when only superficial surface changes are required and extensive skeletal destabilization can be avoided.

Unlike postrhinoplasty deformities of skeletal tissue *excess* that are often the result of incomplete surgical treatment, postsurgical deformities of skeletal *deficiency* are commonly the result of aggressive overtreatment. In the so-called "overresected nose," excessive lowering of the nasal bridge and/or overzealous excision of the nasal tip cartilage results in a profound and often progressive collapse of the nasal framework. The cosmetic impact of surgical overresection is an unattractive and stigmatic look that is derived from an amalgamation of various characteristic nasal deformities (Fig. 184.2A–C). Surgical overresection of the alar cartilages, particularly the lateral crura, frequently leads to pinching of the nasal tip, alar retraction, bossae, and/or supra-alar pinching, while overresection of the anterior septum may lead to overrotation or excessive deprojection of the tip unit (1–3). Moreover, overresection of the anterior septum will typically weaken skeletal tip support and exacerbate the adverse effects of alar cartilage overresection (1,4). Finally, overresection of the nasal dorsum leads to a scooped dorsal profile, often accompanied by middle vault pinching, a widened and washed-out bony dorsum, and abnormal shadowing of the bony–cartilaginous junction—the so-called inverted-V deformity (3,5) (Fig. 184.3). In addition to a conspicuous and unsightly nasal appearance, the overresected nose is also emblematic of bad rhinoplasty surgery—a highly undesirable stigma that adds to the patient's emotional distress. Unfortunately the morbidity of surgical overresection is not limited to cosmetic sequelae as most overresected noses are also burdened by collapse of the internal and/or external nasal valves leading to symptomatic nasal airway obstruction (1–3). Overresection of the nasal framework is a devastating complication of cosmetic rhinoplasty that usually leads to severe nasal deformity and that likely represents the most common motivation for revision rhinoplasty.

In order to restore the overresected nose to create a sturdy, attractive, and fully functional appendage, revision rhinoplasty requires *re-expansion* of the undersized and collapsed skeletal framework—frequently against a scarred and inelastic soft tissue envelope. Unlike naturally elastic nasal skin that can stretch to accommodate full skeletal re-expansion, fibrotic and noncompliant skin may fail to permit cosmetically and functionally ideal enlargement of the nasal framework. Moreover, successful skeletal re-expansion requires a newly constructed framework of sufficient rigidity to distend the scarred and noncompliant nasal skin without invoking skeletal distortion, all while simultaneously avoiding cutaneous vascular insufficiency produced by excessive closing tension and subsequent disruption of nutrient blood flow. In patients with medical comorbidities such as cigarette smoking, diabetes, inflammatory disease, prior cocaine abuse, or any other form of preexisting vascular impairment, the risk of vascular insufficiency is greatly increased, and excessive skin tension must be carefully avoided even if the newly expanded framework must be reduced in size. Accordingly, a thorough history and physical examination is particularly important in this patient population to screen for risk factors or preexisting manifestations of impaired tissue perfusion. Although frank skin necrosis is exceedingly rare in revision rhinoplasty, vascular insufficiency may still result in wound dehiscence, incomplete revascularization of autografts, and/or frank wound infection—any of which may potentially jeopardize the surgical outcome and produce disastrous surgical consequences. Consequently, in the overly short and underprojected nose with stubbornly noncompliant nasal skin, avoidance of vascular compromise often precludes full skeletal re-expansion and this limitation is best identified and discussed prior to surgery. Moreover, even in the absence of skeletal re-expansion, tissue perfusion is disrupted to some degree in every rhinoplasty, and proactive measures to optimize tissue perfusion are essential. Meticulous soft tissue technique, judicious use of electrocautery, appropriate use of surgical dissection planes, avoidance of overly constrictive compression dressings, careful monitoring of capillary refill, and postoperative supportive measures all serve to collectively optimize soft tissue perfusion and reduce the risk of ischemic injury. Without question, the combined skeletal and soft tissues derangements associated with the overresected nose make it one of the most technically challenging and complication-prone of all postsurgical nasal deformities.

In reality, most severe surgical deformities are a combination of overresected skeletal tissues and untreated deformities of the original nose. Coexisting nasal airway dysfunction is common, and twisting and/or asymmetry of the damaged framework is also frequently present, both of which make revision rhinoplasty considerably more complicated. And while a severely disfigured nose presents

A

B

C

Figure 184.2 Typical cosmetic and functional stigmata of the overresected nose. **A:** Lobular pinching and alar retraction on frontal view, **(B)** severe alar retraction and poor tip projection on profile view, and **(C)** lobular pinching and nasal valve collapse on basal view.

Figure 184.3 Frontal view of the "inverted-V" nasal deformity. Note disruption of the brow-tip aesthetic lines and the distinctive inverted-V shaped shadow traversing the nasal dorsum.

a formidable and sometimes insurmountable technical challenge, the presence of coexisting psychosocial issues can also greatly complicate the management of any rhinoplasty patient.

PATIENT EVALUATION AND TREATMENT PLANNING

Regardless of whether the surgical challenge is big or small, the ultimate objective of revision rhinoplasty is always the same—to create an attractive, sturdy, and fully functional nose that flatters the face and integrates naturally with the surrounding facial features. However, this task is not always easy or even medically feasible, and deciding when and how to operate is the first critical step in a successful revision rhinoplasty. Ironically, it is often the failure to properly evaluate the nose that leads to revision rhinoplasty in the first place, and the importance of the preoperative nasal history, physical examination, and cosmetic analysis cannot be overemphasized. Although the novice surgeon often focuses primarily upon the operative procedure, the accomplished surgeon will spend as much or more time on the evaluation, analysis, and treatment planning as on the operation itself. And because the end result of revision rhinoplasty depends as much upon tissue quality and healing responses as the actual operation, *recognizing* and planning for tissue inadequacies is frequently what differentiates a favorable outcome from a disappointing one.

For the revision rhinoplasty patient, the initial nasal assessment begins with a thorough rhinoplasty history detailing the number of prior surgeries, the recovery interval between surgeries, the specific intervention for each surgery, and the subsequent tissue responses. This information serves to characterize the type and degree of prior tissue alteration and the overall wound-healing tendencies. When combined with the results of a thorough nasal examination, the rhinoplasty history will reveal the approximate anatomic and physiologic health of the nose and its likely tolerance for additional surgery. From this baseline perspective, the surgeon must then analyze the cosmetic deformity, pinpoint the desired cosmetic and functional end point, and devise an effective surgical game plan that accounts for the existing anatomic and cosmetic inadequacies. A careful assessment of the existing structural support, airway patency, nasal contour, and tissue quality will enable the surgeon to customize the surgical game plan in order to compensate for anticipated tissue deficiencies and/or adverse wound-healing responses. From the psychological standpoint, perhaps the biggest challenge in revision rhinoplasty is establishing realistic cosmetic expectations that coincide with the anticipated surgical complexity and the associated risks and limitations therein. A careful assessment of the patient's personality, underlying motives, and cosmetic objectives is also essential to reduce the likelihood of disappointment and/or confrontation stemming from unmet surgical expectations. Clearly, complex revision rhinoplasty is an intricate and complicated puzzle that can only be solved with a detailed and thorough preoperative evaluation.

PSYCHOLOGICAL ASPECTS OF REVISION RHINOPLASTY

From the moment of introduction, an evaluation of the patient's emotional health and well-being should commence. To begin the consultation, the surgeon should review the patient's social history, including the patient's education, employment, marital status, living situation, and psychiatric history. This information will help to delineate the patient's level of functioning and to define his or her emotional support network. As the consultation proceeds, the surgeon should also carefully explore the patient's justification for seeking revision rhinoplasty and the patient's concept of a satisfactory outcome. In most instances, healthy patient motives and realistic treatment expectations become increasingly evident as doctor/patient relationship develops. However, for patients with discrete emotional pathology, inappropriate motives and/or grandiose surgical expectations are often the first signs of underlying emotional illness. Unfortunately, many serious emotional disorders are not always readily

apparent, and emotionally disturbed patients are often adept at concealing their symptoms. Although the majority of secondary rhinoplasty patients are not suffering from discrete emotional illness, emotional overtones are common in both emotionally unbalanced and emotionally healthy revision patients, making it difficult to properly differentiate between these fundamentally different yet outwardly similar patient groups. And because discrete emotional disorders are often more difficult to identify in the revision rhinoplasty patient, the consulting surgeon should maintain a high index of suspicion in any patient who exhibits subtle signs or symptoms suggestive of emotional pathology. Although detecting emotional illness is sometimes challenging, the importance of early identification is paramount since surgical treatment is often contraindicated in patients with discrete psychological disorders; and failure to properly screen for emotional pathology may lead to potentially catastrophic treatment complications.

As stated above, psychological evaluation of the revision rhinoplasty patient is made more challenging by the normal, yet sometimes alarming emotional overtones that typically accompany a failed rhinoplasty. While these emotional overtones manifest differently among revision rhinoplasty patients according to a variety of factors, the typical *primary* rhinoplasty patient is generally far less complicated from an emotional standpoint. For surgeons unfamiliar with the emotional by-products of a failed rhinoplasty, behavior of the typical (well-adjusted) *revision* rhinoplasty patient may occasionally seem both inappropriate and disconcerting, particularly when compared to the happy-go-lucky primary rhinoplasty patient. Consequently, understanding and appreciating the unique emotional context of the revision rhinoplasty patient is fundamental to appropriate patient selection and successful patient management.

For the typical first-time (primary) rhinoplasty patient, the prospect of an attractive and unobtrusive nose is a long-sought personal goal that is the motivating force behind surgical treatment. Characteristically, the first-time rhinoplasty patient is upbeat and excited about surgery, since it promises to beautify a nose that was often a source of insecurity, embarrassment, or social ridicule. Any fears or apprehensions generated by the anticipated discomfort or potential risks of surgery are often quickly dispelled by the prospect of an attractive new facial appearance. In fact, the typical primary rhinoplasty patient often approaches the surgery with carefree optimism, focused primarily upon the promise of a favorable cosmetic outcome.

In contrast, for the typical *revision* rhinoplasty patient, the bitter disappointment of a failed rhinoplasty gives rise to a far more pessimistic outlook dominated by apprehension, worry, and skepticism. For most revision patients, the emotional nightmare that prompted secondary rhinoplasty is not easily forgotten, and further treatment is seen through a much more ominous perspective. Frequently the prospective revision rhinoplasty patient is skeptical, indecisive, and hesitant to risk further facial deformity despite a favorable prognosis for a successful restoration. As a consequence, many patients awaiting revision surgery repeatedly second-guess their treatment decision and become increasingly more anxious as surgery approaches.

The apprehension and lack of confidence typical of the revision rhinoplasty patient is easy to understand. Rather than the attractive and natural-appearing nose that was anticipated, the revision rhinoplasty patient has been forced to contend with unexpected facial disfigurement and the array of unpleasant human emotions that naturally accompany an adverse life event. The realization that their surgeon may have been inexperienced and poorly trained, or even incompetent and deceitful, is often very difficult to accept, particularly if surgery was preceded by repeated assurances that a favorable outcome was a virtual certainty. Accordingly, confusion, bewilderment, embarrassment, resentment, anger, and mistrust often characterize the initial response to a failed cosmetic rhinoplasty. And for the emotionally frail and insecure individual who lacks strong coping skills, the psychological impact of a failed rhinoplasty is typically far more severe and disabling. Moreover, for patients with frank psychological disorders, a failed rhinoplasty may provoke considerable anger and resentment resulting in a wide range of maladaptive and aberrant behaviors. Hence the prospect of further surgery in the previously operated patient is a much different undertaking that must be approached in a far different manner.

Fortunately, most revision rhinoplasty patients are well-adjusted individuals who are reacting in a justifiable manner to an unanticipated facial deformity. And although even well-adjusted individuals must reconcile the negative human emotions that inevitably attend a failed rhinoplasty, once beyond the initial shock and disappointment of an adverse outcome, the well-balanced individual quickly rebounds and seeks appropriate restorative treatment. Eventually, anger and disappointment are channeled in a healthy and productive manner—ultimately leading to a rational plan of action and resolution of the problem.

In contrast, for those with poor coping skills, a failed rhinoplasty can become an emotionally devastating event heralded by withdrawal, self-pity, and depression. Extreme insecurity and social isolation are not uncommon in this patient population, and in severe cases may even lead to loss of employment, disruption of schooling, and/or failed interpersonal relationships. Despite their yearning for an attractive nose, the emotionally insecure patient often becomes paralyzed with apprehension and may wait years before finally deciding to undertake revision surgery. For others, the longing for a normal-looking nose is superseded by the fear of yet another failed outcome, and despite a favorable surgical prognosis, surgery is never undertaken.

Finally, a small number of revision rhinoplasty patients also suffer from underlying psychological illness. In addition to the already substantial technical challenges typical

of complex revision rhinoplasty, management is further complicated by active resistance to patient counseling, a lack of rational decision making, and disregard for surgical restrictions and care requirements. In some instances, psychological disturbances may even render the patient incapable of assessing their postrhinoplasty outcome with any degree of objectivity. Regardless of whether or not these patients have legitimate cosmetic abnormalities, their inability to acknowledge previously damaged nasal tissues, subsequent treatment limitations, inherent surgical risks, and/or actual surgical improvements makes them exceedingly poor surgical candidates irrespective of their surgical prognosis. Failure to identify such individuals and to defer surgical treatment can lead to anger, confrontation, hostility, and potentially even violence against the surgeon or the surgical staff; and such problems underscore the importance of careful patient screening during the initial evaluation.

Although most revision rhinoplasty patients are well-adjusted individuals, for even the most self-assured and emotionally secure individual, the initial impact of a failed surgery is substantial and can be exacerbated by absent family support, severe disfigurement, insufficient financial resources, or limited access to appropriate medical care. Instead of enjoying the physical and emotional benefits of an attractive new nose, the failed rhinoplasty patient must contend with the prolonged public stigma of a "botched nose job," and the prospect of a second more difficult, and frequently more expensive, revision surgery. Even individuals with robust coping mechanisms and a strong emotional support network will suffer some measure of angst in this scenario, and the revision rhinoplasty surgeon must make allowances for these difficult circumstances (6). At the very least, the revision rhinoplasty surgeon should regard all prospective revision patients, including those with healthy coping skills, as emotionally traumatized, potentially labile, and justifiably distraught individuals. Without question, the addition of powerful and unpredictable emotions superimposed upon a formidable technical challenge make revision rhinoplasty patients exceptionally difficult to treat (6,7).

Perhaps one of the most difficult aspects of revision rhinoplasty is establishing a bond of trust with the apprehensive and cautious secondary rhinoplasty patient. Having previously placed their trust in a medical professional they assumed would beautify their nose, the typical revision rhinoplasty patient often finds it difficult to trust another surgeon, much less to then embark upon a more difficult and more hazardous secondary operation. Since many adverse rhinoplasty outcomes result from substandard surgical care, a cautious and skeptical approach to further surgery is clearly justified but may itself become an obstacle to the ultimate goal of nasal restoration. Furthermore, most revision rhinoplasty patients resort to the Internet for treatment advice where confusing and often erroneous recommendations are commonplace. The Internet also provides interactions with hundreds of other unhappy rhinoplasty patients serving to underscore the prevalence of adverse outcomes and to further raise the level of patient anxiety. Sadly, the Internet often portrays rhinoplasty surgeons as uncaring and profit-driven individuals who prey upon the unsuspecting. And while the unethical and incompetent practices of some cosmetic surgeons may lend credence to these cynical viewpoints, the emotionally traumatized and gullible revision rhinoplasty patient is particularly susceptible to such distortions and may erroneously regard these views as both authoritative and trustworthy. Consequently, the prospective revision rhinoplasty patient often initially regards the treatment recommendations of the revision rhinoplasty consultant with suspicion and mistrust. Even multiple consultations with seasoned revision rhinoplasty experts may fail to provide clarity and reassurance, particularly since legitimate differences in treatment philosophy often result in contradictory treatment recommendations. Hence, while the secondary rhinoplasty patient is often eager to treat the postsurgical deformity, they are often confused and uncertain about where to turn for help.

Upon the realization that further nasal surgery is inevitable, most revision rhinoplasty patients seek to become more knowledgeable as to the methods, risks, and options for revision nasal surgery. As a result, patients occasionally demonstrate a surprising familiarity with technical rhinoplasty jargon and tout a (cursory) understanding of secondary rhinoplasty techniques. Moreover, they will often challenge the technical aspects of a proposed treatment plan based upon a naive and sometimes distorted understanding of nasal surgery. At face value, these patients may seem overly controlling and manipulative—much like the individual with narcissistic personality disorder. However, upon closer scrutiny these individuals are usually nothing more than fearful victims who are desperately trying to avoid yet another devastating surgical outcome, and the revision rhinoplasty surgeon should not necessarily be intimidated by patients seeking validation of the proposed treatment plan.

Without question, a failed rhinoplasty has numerous medical, financial, and psychosocial implications for the patient. Moreover, the task of finding a trustworthy surgeon with appropriate skills and expertise can prove a daunting and frustrating task for the gun-shy patient, particularly when conflicting opinions and misinformation abound. Since many prospective patients harbor concerns about the integrity, professionalism, and surgical competence of the revision surgeon, a compassionate listening ear and a willingness to patiently justify all treatment recommendations is the first step in earning patient trust and confidence. Failure to effectively justify the proposed treatment plan or to provide a compelling rebuttal to various misguided treatment recommendations, no matter how painstaking or time-consuming, may ultimately foster mistrust and create an emotional barrier to successful revision surgery.

And although a trusting relationship takes considerable time and effort to cultivate, it is highly improbable that a revision rhinoplasty patient will progress to surgical treatment without it.

SOMATOFORM AND PERSONALITY DISORDERS

Despite the commonly held view that cosmetic nasal surgery is merely a superficial (nontherapeutic) alteration of outward appearance, significant psychological benefits have been confirmed in well-adjusted individuals following successful primary rhinoplasty (8,9). Moreover, it is reasonable to conclude that similar therapeutic benefits are likely for the *revision* rhinoplasty patient since a successful outcome can fully eliminate the cause of emotional angst and provide analogous psychological benefits. However, roughly one-third of individuals seeking cosmetic nasal surgery also present with symptoms of mild to moderate psychiatric disease (8,9). Included among this subset of patients are those with distinct and identifiable psychological disorders such as somatoform disorders or various forms of aberrant personality disorders. In both cases, these disorders may thwart successful treatment, and the treating surgeon must be familiar with the hallmark symptoms of each disease so that appropriate precautions and/or exclusions can be implemented.

Body dysmorphic disorder (BDD) is a somatoform disorder that occurs at a far greater frequency among patients who seek cosmetic surgery (9–11). Sometimes called "imagined ugliness syndrome," BDD is a DSM-IV disorder (Diagnostic and Statistical Manual of Mental Disorder, Fourth Edition) that is defined as an irrational preoccupation with an imagined or trivial defect in appearance that results in significant emotional distress and/or impairment in daily functioning. Nearly all BDD sufferers engage in compulsive behaviors such as mirror checking or skin picking related to obsessive preoccupations with personal appearance, often spending hours each day engaged in these anxiety-producing activities (9–11). In severe forms, BDD may give rise to surgically addictive behaviors in a futile quest to eliminate imaginary flaws in body image. However, nonpsychiatric medical treatments such as cosmetic surgery seldom prove effective in eliminating symptoms of BDD (9,12). The most common form of BDD is the delusional variant in which patients lack insight or awareness regarding their obsession; whereas patients with the nondelusional variant can recognize their obsession to a variable extent (11). In the delusional form, sufferers are completely convinced that they appear ugly and grossly abnormal. Frequently BDD occurs in tandem with other psychiatric disorders including major depression, obsessive-compulsive disorder, substance abuse disorder, eating disorders, and personality disorders (9). Impaired psychosocial functioning is common in BDD and in severe cases may result in prolonged school or work absences, or the inability to sustain interpersonal relationships (11). Clinical depression is a near-universal feature of BDD, and patients with severe BDD are at significantly increased risk for suicide (10,11). Revision rhinoplasty surgeons are also likely to encounter BDD patients with far greater frequency as the nose is one of the most common areas of concern second only to the hair and skin (10). Interestingly, BDD sufferers also frequently "doctor shop" as they relentlessly seek a surgical cure to their psychiatric illness (9,10). However, in contrast to well-balanced patients with mild but correctable complaints who will benefit from successful revision surgery, those with BDD may never achieve satisfaction regardless of the cosmetic outcome. Even exceptional cosmetic outcomes are unlikely to eliminate the patient's dissatisfaction with their nasal contour and may even trigger new obsessions with other body parts (9,10). Physical violence is also more common in distraught BDD patients and may be directed at cosmetic surgeons who fail to eliminate the perceived deformity (9–12). Because many BDD sufferers are adept at evading the screening process, the diagnosis of BDD should be entertained in any patient who dwells excessively upon a minimal or barely perceptible cosmetic defect. In a recent survey of 265 aesthetics surgeons regarding BDD, 84% failed to recognize symptoms of BDD until after surgery (12). Because surgical success rates are exceedingly poor in patients suffering from BDD, particularly delusional BDD patients in whom appropriate insight is lacking, surgery is generally contraindicated (9,11). Psychiatric evaluation and treatment is recommended for any individual in whom BDD is suspected, particularly since the delusional variant appears to respond to drug therapy with serotonin reuptake inhibitors (10,11). Psychiatric clearance is also essential for any suspected BDD patient prior to cosmetic surgical treatment (10), but surgical success rates in patients with documented BDD are notoriously poor and there is a growing consensus that BDD should be regarded as a contraindication to cosmetic treatments (9,11).

Personality disorders, defined as deeply ingrained, nonpsychotic, and maladaptive patterns of behaving and relating to others, are the most commonly encountered psychological disturbance in patients seeking cosmetic surgery (6,13). Although certain personality disorders are easily recognized, others such as borderline personality disorder may be difficult to identify since patients may initially seem normal. The borderline personality disorder is characterized by a sense of loneliness and emptiness, unpredictable mood swings, fear of abandonment, and irritability (6). Patients with borderline personality disorder may be identified as slightly "off" due to excessive flattery and premature familiarity, juxtaposed against aggressive and suspicious questioning. Despite behavior that is initially flattering, sympathetic, or seductive, stressful events such as a failed rhinoplasty (or a perceived surgical failure) may trigger acute decompensation with overt maladaptive symptoms such as postoperative depression,

disordered self-image, and/or inappropriate demonstrations of anger, as individuals with borderline personality disorder look to others for cause, responsibility, and blame for their actions or circumstances (6,13).

Another commonly encountered personality disorder, the narcissistic personality disorder, is characterized by excessive arrogance and a feeling of superiority to others, regardless of actual achievements (6). Patients with narcissistic personality feel entitled to special treatment from office staff and the surgeon due to an inflated sense of self-esteem. Narcissists require continual validation of their special status and react with indifference, contempt, or even hostility to those who fail to actively reinforce their self-perceived greatness. Often they wear conspicuous flashy clothing or makeup and behave in a way that is designed to attract attention. Consequently, the narcissistic personality is typically very easy to discern in consultation. They interrupt frequently, demonstrate resistance to active listening, and show disinterest in surgical recommendations as they typically possess a preconceived notion of what procedure is best for them. While the otherwise normal but self-centered or egotistical individual may make a suitable surgical candidate when they are able to acknowledge the limitations of surgical treatment, elective cosmetic surgery is generally contraindicated in the patient with frank narcissistic personality disorder (6). Moreover, failure to meet the unrealistic cosmetic expectations of the narcissistic patient may trigger a narcissistic rage that can be disturbing, frightening, and even physically violent.

When evaluating any prospective rhinoplasty patient, it is critically important for the revision rhinoplasty surgeon to look beyond the technical aspects of surgical treatment and to closely examine the psychological health of the individual as demonstrated through the developing surgeon–patient relationship. Virtually all revision rhinoplasty patients present with some measure of recent or current emotional upheaval in response to the adverse rhinoplasty outcome, making detection of emotional pathology far more difficult. However, for the emotionally healthy individual, the normal response to a stressful adverse life event does not ultimately inhibit effective management. In contrast, for patients with various emotional disorders, the absence of insight and/or objective thinking makes attaining a satisfied patient highly improbable, and treatment is usually best avoided altogether. Failure to recognize the differentiating signs and symptoms of these emotionally troubled patients may result in significant conflict between patient and surgeon even when the surgical care is appropriate and the surgical outcome is satisfactory. In extreme cases, maladaptive behaviors may lead to confrontation, hostility, and potentially even physical violence. And with the recent popularity of Internet communication, hostility may also manifest through online slander, character assassination, and/or fictitious accounts of surgical negligence, all protected by the cloak of Internet anonymity. Clearly, a failed rhinoplasty is an emotionally charged issue, and the revision surgeon must always be mindful of the significant emotional overlay associated with treatment expectations, particularly in the presence of underlying emotional pathology.

KEY PROGNOSTIC INDICATORS IN SECONDARY RHINOPLASTY

Proper physical evaluation of the revision rhinoplasty patient includes an assessment of several key determinants that strongly impact the surgical prognosis. The importance of these determinants to successful secondary rhinoplasty merits special emphasis during the nasal examination and each of these variables is briefly highlighted below.

In addition to evaluating the psychological well-being of the patient, the initial patient evaluation should focus upon the patient's general medical health, particularly as it relates to anesthetic tolerance and surgical wound healing. Although robust general health, good exercise tolerance, and the absence of medical comorbidities are favorable indicators of physical vigor at any age, secondary nasal surgery becomes increasingly more difficult in later life. In contrast to adolescents and young adults who typically possess a dramatic and rapidly forgiving recuperative capacity, elective cosmetic nasal surgery is often far more prone to complications in middle age and beyond. While general physical vitality remains an important consideration in all patients, age alone is a major consideration in cosmetic nasal surgery, particularly in the previously operated nose. Hence, complex revision rhinoplasty should be approached with caution in the older patient since nasal healing responses often decline with age.

Another important prognostic indicator is the length of time since prior nasal surgery. Although surgically induced tissue trauma is to a large extent permanent and therefore cumulative, at least some degree of tissue injury is reversible if given adequate time for recovery. Consequently, multiple surgical procedures stacked at close intervals are highly detrimental since the nose has yet to recover from one injury before being subjected to another. In this scenario, even a young healthy patient with highly favorable recuperative powers may develop adverse wound-healing responses due to repeated uncompensated tissue trauma. Conversely, a healthy 35-year-old patient seeking revision of a failed teenage rhinoplasty has the advantage of a nearly two decade-long recovery in which all reversible injury has fully resolved. In this scenario, a well-executed revision rhinoplasty in a suitable candidate is usually followed by favorable wound-healing responses, sometimes comparable to a previously unoperated nose. Hence, noses that have been allowed a prolonged period of recovery are often far more tolerant of secondary surgery, whereas revision surgery in the face of acute swelling and inflammation may lead to increased complication rates from adverse healing responses.

Another critical factor that can dramatically impact the surgical prognosis is nasal skin quality. Without question, a smooth and healthy nasal complexion with intermediate skin thickness is best suited to cosmetic nasal surgery. In fact, a clear, smooth (nonsebaceous) complexion almost always indicates tolerant and "forgiving" nasal skin with minimal scarring tendencies and little preexisting cutaneous inflammation. On the other hand, thick oily nasal skin with large sebaceous units often responds poorly to surgical manipulation, reacting with excessive swelling, prolonged inflammation, and a tendency for heavy subcutaneous scarring. In the oversized nose, thick inelastic skin may fail to contract and properly conform to surgical reduction of the skeletal framework, whereas in the undersized nose, thick inelastic skin may limit cosmetically ideal skeletal re-expansion. Another important disadvantage of ultrathick nasal skin is the loss of surface definition created by excessive *masking* of the underlying skeletal framework. Because ultrathick nasal skin heavily obscures topographic features of the underlying nasal skeleton, the delicate surface undulations that characterize a well-defined and attractive nasal tip are lost. Moreover, a weak and underprojected nasal framework, whether acquired naturally or through surgical overresection, only serves to exacerbate the loss of desirable surface highlights. In contrast, for patients with extremely *thin* nasal skin, the atretic outer covering offers scant camouflage of underlying skeletal imperfections, and a flawless skeletal contour is required to prevent visible imperfections in the surface topography. Furthermore, both telangiectasias and dyschromias are easily provoked with repeated surgical dissection of thin nasal skin. In contrast to ultrathick or ultrathin nasal skin, intermediate skin thickness offers effective concealment of minor skeletal imperfections while still retaining a well-defined and attractive surface contour. In addition, healthy skin of intermediate thickness is usually associated with ample elasticity, prompt resolution of surgical edema with minimal subcutaneous scarring, and the capacity to rapidly conform to a surgically downsized nasal framework. When examining the previously operated nose, nasal skin quality is a crucial prognostic indicator that must be evaluated carefully. In fact, nasal skin *quality* is typically a far more reliable indicator of wound healing than is skin pigmentation, as virtually all skin tones will heal favorably when the complexion is smooth and clear. Consequently, failure to assess skin quality and to account for the intrinsic healing characteristics during surgical planning is a serious oversight in the evaluation process.

Another critical determinant of surgical success is intrinsic cartilage strength. Because the goal of any rhinoplasty is to create a permanent improvement in nasal contour via a *nondeforming* and durable skeletal framework, the biomechanical properties of the nasal cartilage are of critical importance to the long-term surgical outcome. Although cartilage strength is commonly regarded as unchanging throughout life, in reality cartilage stiffness commonly degrades over time. Age-related or disease-mediated losses in cartilage strength are inevitable in virtually every nose, and while noses blessed with naturally rigid cartilage may experience only negligible losses in structural support, in noses with naturally soft cartilage, age or disease-mediated deterioration may profoundly affect the shape and/or function of the nose over time. Moreover, even modest cartilage resection can exacerbate the age-related or disease-mediated deterioration of naturally weak nasal cartilage, producing a catastrophic effect upon long-term structural integrity. Vigorous soft tissue contraction—the so-called "shrink wrap" phenomenon—may compound the adverse impact of surgical intervention and age-related deterioration by distorting and collapsing the severely weakened nasal framework. Consequently, when evaluating the previously operated nose, baseline skeletal strength becomes a key indicator of both the existing structural support and the future susceptibility to structural failure. And since surgical restoration of the nose is only as good as the tissues used in the reconstruction, assessment of the baseline structural integrity *and* the strength of available graft materials are critical to the surgical prognosis and represent a crucial component of every new patient evaluation.

The final prognostic indicator is perhaps the most important single factor in the surgical prognosis—the body's genetically predetermined response to tissue injury. While the majority of young healthy individuals enjoy a forgiving tissue response that facilitates rapid and favorable healing, a small subset of humans appear to have tissues that respond poorly to surgical manipulation regardless of the care and precision exercised during surgical treatment. Furthermore, this sinister tendency is nearly impossible to detect with certainty in any given patient. Unlike the aforementioned prognostic indicators that can be quantified during the new patient evaluation, unfavorable wound healing responses may occasionally present without any identifying signs or symptoms. And while the majority of unsuccessful rhinoplasties are probably the result of incorrect aesthetic analysis, poor artistic judgment, technical errors, or surgical incompetence, a small subset of adverse outcomes is unquestionably the result of genetically predetermined adverse would-healing tendencies. At their worst, unfavorable healing responses may lead to prolonged inflammation, excessive fibrosis of the soft tissue envelope, excessive or inadequate soft tissue contracture, vascular insufficiency, and/or diminished immune function. The cumulative effects of these antagonistic influences may completely negate all of the surgical modifications intended to enhance nasal contour and function. Moreover, adverse wound-healing responses often become more severe with each successive nasal surgery. Although physical signs such as thick inelastic nasal skin, hypertrophic scarring, or excessive subcutaneous fibrosis often foreshadow adverse wound-healing responses, hostile healing responses can also arise in seemingly favorable surgical candidates who are devoid of discrete clinical findings.

When combined with weak skeletal anatomy in the surgically damaged nose, adverse healing responses represent an insurmountable surgical challenge in which further surgery is best avoided. Because these patients are occasionally indistinguishable from those with normal healing responses, even the accomplished surgeon will occasionally experience an adverse surgical outcome despite performing a technically appropriate and well-executed surgical procedure. Consequently the prudent surgeon should forewarn all patients about the unlikely but potentially catastrophic development of adverse healing responses, and a favorable surgical outcome should never be guaranteed even in the seemingly ideal patient. Although physical signs and symptoms are often lacking, warning signs suggestive of adverse healing responses should be sought in every new patient evaluation.

PHYSICAL ASSESSMENT OF THE NOSE

Perhaps the most commonly neglected, yet critically important component of the revision rhinoplasty assessment is physical examination of the nose. Because every secondary rhinoplasty patient presents with varying degrees of prior surgical scarring, skeletal disruption, vascular impairment, and/or structural instability; a proper revision rhinoplasty evaluation requires a thorough physical examination and *cannot* be conducted by photo review alone. Although photographic analysis of the nose is a critical component of the preoperative cosmetic assessment (5), high-resolution rhinoplasty photos fail to convey vital physical and biomechanical tissue properties like cartilage strength, tip support, sidewall rigidity, skin thickness, airway dimension, septal alignment, valve patency, or skin elasticity. In the aggregate, these tissues characteristics have a profound influence upon the method of surgical treatment and upon the probability of a successful surgical outcome. Failure to carefully examine the previously operated nose with a combination of inspection, palpation, and dynamic observation is a grave oversight that often precedes unsuccessful surgery. Hence, the present trend toward Internet consultations, while a reasonable first step in the evaluation process, should not be regarded as a suitable substitute for a proper one-on-one patient evaluation.

Surgical assessment of the nose prior to revision rhinoplasty requires a methodical physical examination designed to assess every physical characteristic that may influence the surgical outcome. The preoperative examination should be conducted in light of the patient's cosmetic and functional objectives so that a realistic treatment plan can be devised that reflects the patient's cosmetic goals and yet simultaneously recognizes and accounts for the anatomic obstacles to success. Although a proper surgical assessment cannot be performed from photographs alone, examination findings should be carefully correlated with standardized rhinoplasty photographs in order to obtain a complete and accurate cosmetic analysis. Indeed, a conventional aesthetic nasal analysis using standardized rhinoplasty photographs is an essential component of every good rhinoplasty evaluation (5). In addition to the cosmetic assessment, the preoperative nasal examination should also evaluate the structural integrity of the bony and cartilaginous skeletal framework; the thickness, elasticity, and perfusion of the inner and outer nasal lining; and the status of the entire nasal airway including the external and internal nasal valves, the nasal septum, and the nasal turbinates. In turn, this information will help to determine the associated surgical complexity, the surgical risk, and the surgical prognosis specific to each individual patient. Although this represents a time-consuming endeavor, without a comprehensive preoperative surgical evaluation the probability of a satisfactory final outcome is greatly diminished. Hence, the importance of the physical examination cannot be overemphasized.

Perhaps the most neglected aspect of the revision rhinoplasty evaluation is the functional assessment of the nose. Often the revision rhinoplasty patient is focused solely upon the cosmetic deformity and is reluctant to further complicate their management with complaints of functional impairment. However, nasal airway dysfunction is common in the revision rhinoplasty patient population and since untreated nasal airway dysfunction can lead to adverse health consequences, particular attention should be directed toward evaluating nasal airway patency. Typically, patients with nasal airway obstruction report daytime nasal congestion that becomes noticeably more severe at night. Subsequent nocturnal obstruction leads to associated symptoms of mouth breathing often accompanied by an overly dry throat, frequent awakenings from thirst or nasal obstruction, and disrupted sleep patterns with daytime fatigue. Ancillary symptoms such as rhinogenic headaches, decreased sense of smell, recurrent sinus infections, or Eustachian tube dysfunction may also be present. Symptoms of allergic rhinitis, when present, will also typically exacerbate the clinical symptoms of nasal airway dysfunction.

For a thorough cosmetic assessment, physical examination of the previously operated nose should include a careful inspection of both the external *and* internal nasal anatomy. In addition to the standard external cosmetic parameters of contour, alignment, symmetry, width, length, projection, and rotation, particular attention should also be paid to the physical and biomechanical characteristics of the outer nose, and *palpation* is an indispensible component of the physical examination. Only palpation will yield information regarding skin thickness, skin elasticity, cartilage strength, sidewall rigidity, tip support, and smoothness of the nasal dorsum. These characteristics are of considerable surgical significance as these physical properties weigh heavily upon the surgical prognosis.

Although important information is obtained through inspection and palpation of the outer nasal tissues, the external nasal attributes tell only part of the story.

Examination of the internal nasal passages is also critically important to the preoperative surgical assessment. Inspection of the nasal vestibule for the presence of cicatricial webs, valvular stenoses, prolapsed crural cartilage, recurvature of the lateral crura, or caudal septal deviations is vital to the complete preoperative assessment of the previously operated nose. In addition, observation of the nose for dynamic nasal valve collapse during normal inspiration is another important part of the physical examination. Findings of dynamic nasal valve collapse are often overlooked on speculum examination and indicate a pathologic weakness of the nasal sidewall—a more common finding in surgically overresected noses. Speculum or fiberoptic examination of the nasal cavum is also a key component of the revision rhinoplasty evaluation. Visual inspection of the nasal mucosa for excessive erythema, rhinorrhea, and edema—the triad of inflammatory findings consistent with allergic rhinitis—should not be overlooked since preoperative allergy treatment may help to reduce both intraoperative bleeding and postoperative mucosal edema. Findings of friable, dry, and heavily crusted mucosa should also be sought since these are tangible signs of decreased vascularity, such as that produced by chronic cocaine abuse, autoimmune vasculitis, or recent surgery. Similarly, visual inspection of the quadrangular cartilage for clinically significant airway obstruction and/or mucosal adhesions (synechiae) is essential since surgical treatment of these fixed anatomic deformities is required for satisfactory functional results. The presence of high (dorsal) deviations of the quadrangular septum should also be sought since a number of cosmetic and functional problems will develop if curvature of the dorsal septum is unrecognized and left untreated. Cotton-swab palpation of the quadrangular cartilage is also recommended to assess intrinsic cartilage strength and to detect potential areas of missing cartilage from previous septal surgery. Stout rigidity throughout the quadrangular septum indicates a reasonable likelihood that surplus septal cartilage is available for cartilage grafting. Septal perforations should also be sought on preoperative examination since large perforations may indicate poor vascularity and compromised structural support of the septal L-strut. While asymptomatic septal perforations do not necessarily require surgical treatment, smaller perforations are often easily eliminated during standard septal surgery and all preexisting anatomic abnormalities should be documented prior to surgical revision. Finally, visual assessment of the inferior and middle turbinates for hypertrophy and obstruction of the internal nasal airway is also necessary for proper functional assessment and treatment.

While no two revision rhinoplasty cases share identical nasal anatomy, many revision rhinoplasty patients present with a stereotypical and stigmatic nasal contour resulting from overaggressive excisional rhinoplasty. In fact, the typical revision rhinoplasty patient presents with at least some functional and cosmetic consequences of inadequate structural support stemming from overzealous skeletal resection. Characteristic stigmatic findings include low dorsal height and ill-defined sidewall shadows, pinching of the middle nasal vault and/or nasal tip with corresponding obstruction of the nasal valve, retraction of the alar rims with notching of the alar margins, and asymmetries of the nasal tip due to unequal scarification and collapse of the alar cartilage remnants. Often these deformities are interspersed with untreated deformities of the original nose such as excessive columellar protrusion, overprojection of the nasal spine, derangements in tip projection, or residual segments of dorsal overprojection such as the pollybeak deformity. Although each patient presents with a unique set of cosmetic and functional abnormalities, the vast majority of complex revision rhinoplasty patients present with varying degrees of *inadequate skeletal support* with or without simultaneous skeletal malposition.

Without question, one of the most important causes of the unsatisfactory rhinoplasty outcome is poor central tip support. In general, noses with naturally weak and/or surgically weakened central tip support are far more prone to adverse rhinoplasty outcomes and to adverse manifestations of alar cartilage overresection. In contrast, patients with vigorous central tip support suffer fewer complications of alar cartilage overresection all other factors being equal (see Case Two). While central tip support is derived in part from direct contributions of the medial crura, as well as from secondary support mechanisms from the surrounding soft tissues, the cartilaginous nasal septum is arguably the most important component of central tip support in most noses. Moreover, in the tension-nose deformity, septal support may comprise the overwhelming majority of structural tip support (14). In a fresh cadaver study examining septal contributions to nasal tip support, Adams and coworkers observed a 3.3-mm average loss in tip projection following isolated (dorsal) septal reductions of 4 mm performed through the open rhinoplasty approach (4). Moreover, even greater losses in tip projection were observed following removal of the entire quadrangular septum. The authors concluded that the septum likely plays a far more significant role in nasal tip support than previously believed, and is likely *equal* in importance to the lower lateral cartilages and their soft tissue attachments in providing nasal tip support. Consequently, assessing tip support by evaluating the intensity of tip recoil, the strength and rigidity of the anterior septum, and rigidity of the lower lateral cartilages is an essential component of the preoperative nasal exam. By the same token, restoring inadequate central support is one of the most important goals of revision rhinoplasty.

PINPOINTING THE COSMETIC OBJECTIVE WITH COMPUTER IMAGING

Without question, a thorough and methodical physical examination is requisite for a favorable surgical outcome. However, assessing the preoperative anatomy is only half of the equation. The other critical element in the preoperative

assessment is the cosmetic objective—how the nose should appear as a consequence of revision surgery. The surgical prognosis will vary considerably according to the ease or difficulty of the cosmetic objective, and pinpointing the desired cosmetic outcome is an essential component of the preoperative assessment.

The ultimate goal of any rhinoplasty, whether primary or secondary, is satisfying the cosmetic desires of the patient. Aside from the formidable technical challenges of revision rhinoplasty, one of the biggest obstacles to achieving a satisfactory cosmetic outcome is obtaining a clear and unambiguous definition of the desired cosmetic objective. Since there is no universal or "ideal" nasal contour that applies equally to all faces (15), pinpointing each patient's specific cosmetic desires is a critical aspect of surgical planning. Increasingly, the typical revision rhinoplasty patient is a young adult with very strong cosmetic preferences. And while many patients have passionate opinions regarding nasal length, tip width, or dorsal contour, many patients also have difficulty effectively articulating their precise cosmetic goals. Moreover, most secondary rhinoplasty patients are seeking reassurance that their goals have been understood correctly, and few are willing to empower the surgeon merely to "do what you think is best."

The advent of computer morphing software, commonly known as preoperative "*computer imaging*," is a helpful new technology that can facilitate communication between the revision surgeon and the prospective revision rhinoplasty patient (5,16). Using standardized, (high-resolution digital) rhinoplasty photographs, combined with computerized morphing software, computer imaging allows the skilled user to electronically edit (or "morph") rhinoplasty photographs in order to visually depict cosmetic surgical enhancements of the nose. Cosmetic analysis of the nose is greatly enhanced using computer imaging since individual parameters such as projection, rotation, width, or length can be altered, either independently or collectively, to determine the aesthetic impact of surgery upon the overall facial appearance. By incorporating the patient's cosmetic preferences into the editing process, lifelike simulations are created that enable the patient to "preview" various surgical changes, and ultimately to endorse the overall cosmetic objective. Because the process yields a concrete representation of the desired cosmetic outcome, a relatively unambiguous goal is established, and both the patient and surgeon are assured that the cosmetic objectives have been communicated effectively. Furthermore, the ability to electronically fade between edited images and the corresponding unedited image in real time greatly enhances the analytical power of computer imaging for surgeon and patient alike. For the patient, real-time transformation provides immediate intuitive understanding of the cosmetic deformity and greater reassurance regarding the proposed surgical correction. For the surgeon, the morphed image offers improved diagnostic insights and a mutually agreeable nasal contour from which an individualized treatment plan can be developed and quantified. Although the benefits of computer imaging are irrefutable, computer imaging is subject to potential abuse and/or misinterpretation. Consequently, care must be taken to avoid overoptimistic simulations and to advise all patients that computer-enhanced images represent a best-case scenario, not a guaranteed outcome (5,16). Nevertheless, while exact recreation of the simulated image is virtually impossible, in skilled hands the final outcome often resembles, or even exceeds, the computer-generated simulation (17). Owing to the many benefits of this new technology, revision rhinoplasty patients now commonly request computer imaging as part of their preoperative surgical assessment.

FINALIZING THE TREATMENT PLAN

Once the cosmetic goal is determined, the final piece of the preoperative assessment is complete. The seasoned revision rhinoplasty surgeon will then carefully collate all of the available information including the patient's general health, the baseline cosmetic deformity, the biophysical tissue characteristics, the patient's cosmetic goals, the extent of functional impairment, the psychological status of the patient, and the likely healing tendencies, in order to devise an individualized surgical treatment plan and a corresponding surgical prognosis. As enumeration of the treatment plan becomes increasingly more explicit, the surgical approach (i.e., external vs. endonasal), the anesthetic options, and the choice of autologous graft materials must also be discussed and agreed upon. The surgeon must then decide if the patient's expectations are realistic and if the treatment objectives are within reach at an acceptable level of surgical risk. The patient's response to the stated surgical limitations and to the overall prognosis will help to determine if patient expectations are appropriate and sincere. Encouraging the patient to articulate and acknowledge the attendant surgical risks also helps to confirm that risk counseling was effective. Finally, the surgeon should ensure that the patient will comply with all surgical restrictions, care requirements, and follow-up appointments before assuming responsibility for surgical care.

Anesthetic Considerations

Once the decision is made to proceed with surgical treatment, preoperative preparations and restrictions are reviewed with the patient. All platelet inhibitors, including aspirin, nonsteroidal anti-inflammatory drugs, omega fish oils, high-dose vitamin E, and most herbal supplements should be discontinued at least 7 to 10 days prior to surgery to prevent drug-induced clotting disturbances. Tobacco users should be advised to discontinue all nicotine products immediately, and nasal allergies should be treated to reduce preoperative inflammation. A general medical evaluation is recommended for any patient with medical comorbidities or potential anesthetic contraindications.

While the optimal type of anesthesia remains a topic of considerable debate, the author emphatically prefers the use of general anesthesia for nasal surgery, and for revision rhinoplasty in particular. A carefully administered general anesthetic titrated to the age and body mass of the patient offers superior patient comfort, improved hemodynamic control, and optimal protection of the lower airway against the threat of aspiration. However, because secondary rhinoplasty cases are typically of a much longer duration than the average primary rhinoplasty, special precautions are required to prevent sequela of prolonged immobility during general anesthesia. All patients are placed in the semi-Fowler "beach chair" position with the feet and head elevated to facilitate peripheral venous return, and the legs are continuously massaged with sequential compression devices to minimize pooling of venous blood in the lower extremities and thereby reduce the risk of deep vein thrombosis. Pressure points on the heels and elbows are padded liberally, and the head is positioned above the heart to minimize venous back-pressure.

While the cost of general anesthesia is marginally greater, the technical advantages of general anesthesia are numerous. First, general anesthesia virtually eliminates intraoperative patient movement in response to painful stimuli. Because the depth of twilight anesthesia is limited by the need to maintain spontaneous ventilation, a partially conscious patient is often prone to unexpected movements and may even become restless, disoriented, or overtly combative. In contrast, endotracheal intubation safely permits a much deeper level of anesthesia that virtually eliminates intraoperative patient movement. Although judicious infiltration of the nose with 1% lidocaine containing epinephrine is still required for optimal hemostasis, distortion of the nose from large fluid volumes can be minimized since pain control is primarily achieved via the general anesthetic. In addition, blood pressure control is far less challenging in the absence of painful stimuli, and controlled hypotension can be used in healthy patients to improve visualization of the surgical field, to minimize extravasation of blood into the surrounding soft tissues, and to minimize operative blood loss. In contrast, patients under intravenous sedation may feel threatened as a result of anesthetic-induced disorientation and confusion. Blood pressure spikes, excessive bleeding, and defensive movements are common in this scenario and may complicate surgical management. While a skillfully administered intravenous anesthetic can often avoid these problems, susceptibility to apnea varies widely among individuals and general anesthesia eliminates this variable entirely. Finally, the presence of a cuffed endotracheal tube provides enhanced protection of the lower airway against the aspiration of blood which is an ever-present risk in upper airway surgery.

Perhaps the biggest perceived drawback to general anesthesia is the high incidence of postoperative nausea and vomiting (PONV). Moreover, PONV is more common following oral ingestion of blood, which is highly emetogenic and common following nasal surgery. In addition to being unpleasant, PONV may also lead to exacerbations in surgical site edema, ecchymosis, pain, and/or epistaxis, potentially prolonging recovery and intensifying the risk of subcutaneous fibrosis. However, a narcotic-free general anesthetic protocol can dramatically reduce the incidence of PONV (*personal observation*). After anesthetic induction with intravenous propofol (APP Pharmaceuticals LLC, Schaumburg, IL) and succinyl choline (PharMEDium Services LLC, Cleveland, MS), general anesthesia is maintained throughout the remainder of surgery on sevoflurane (Abbott Laboratories, North Chicago, IL) inhalational anesthetic. During periods of planned stimulation such as during lateral osteotomies, propofol is first administered by bolus to assist in blood pressure homeostasis and labetalol hydrochloride (Hospira Inc., Lake Forest, IL) or nicardipine hydrochloride (Sandoz Inc., Princeton, NJ) are used to supplement blood pressure and/or heart rate control. Dexamethasone sodium phosphate (APP Pharmaceuticals LLC, Schaumburg, IL) is used on induction for prophylaxis against PONV, and a single 4-mg dose of ondansetron (Baxter Healthcare Corporation, Deerfield, IL) is also used 30 minutes prior to extubation for additional PONV prophylaxis. The combined use of dexamethasone and ondansetron has been shown to be more effective at reducing severe PONV than ondansetron alone for both laparoscopic surgery and fentanyl-based patient-controlled analgesia (18,19). Moreover, by using the narcotic-free general anesthetic protocol described above, postoperative emesis is rare even when oral narcotics are used for postoperative pain control, and most patients are alert and oriented within 10 to 15 minutes of extubation. When used in combination with controlled-hypotensive anesthesia, the protocol also has a favorable impact upon postoperative swelling and ecchymosis since the intraoperative tissue extravasation of blood is greatly minimized. Patients typically perceive their surgery as lasting only a few minutes and few have recall of the operating room experience.

SURGICAL RECONSTRUCTION OF THE PREVIOUSLY OPERATED NOSE

Optimal Timing of Revision Rhinoplasty

The optimal timing of secondary rhinoplasty (and the traditional requirement to postpone surgery for 1 year) is a topic of ongoing debate. For virtually any complex secondary rhinoplasty patient, the emotional burden of a prolonged recovery is considerable, and rapid intervention would be far preferable from an emotional standpoint. However, early revision surgery in the face of *acute* postsurgical inflammation and edema is significantly more complication prone, and is generally best reserved for legitimate medical emergencies. Furthermore, even when the acute

postsurgical changes have resolved, the surgically disrupted capillary and lymphatic microcirculation remains compromised, and complex revision surgery is generally best postponed until soft tissue swelling—the outward manifestation of microcirculatory impairment—has fully resolved. Although waiting a full year before correcting an unsightly postsurgical deformity can result in considerable emotional distress, a healthy microcirculation is essential to any complex secondary rhinoplasty, and the traditional recommendation to postpone revision surgery for 1 year is generally appropriate since significant microcirculatory impairment is often present in the first year after surgery. Moreover, in cases where the nose remains unacceptably large but otherwise shapely, allowing ample time for swelling and edema to resolve may obviate the need for revision surgery altogether since an acceptable cosmetic result often emerges within 12 months. And because surgical swelling is usually far more severe in patients with thick, sebaceous nasal skin, revision rhinoplasty in the ultrathick-skinned patient solely for the purpose of achieving minor size reductions is generally contraindicated for at least 18 to 24 months. Longer healing times are also necessary for patients with significant acne, allergic rhinitis, or other forms of chronic inflammation unless the inflammatory stimulus can be adequately controlled. While prolonged recovery is generally recommended for the thick-skinned or inflammation-prone patient, prolonged lymphedema may also give rise to permanent subcutaneous fibrosis, thereby tainting an otherwise satisfactory cosmetic outcome. Consequently, in patients with prolonged swelling, the judicious use of low-dose triamcinolone acetate injections is often necessary to prevent permanent iatrogenic thickening of the nasal skin (20). Although triamcinolone injections can potentially cause significant adverse side effects such as telangiectasias, dermal thinning, and even cartilage absorption, when carefully titrated, low-dose triamcinolone can greatly enhance the cosmetic outcome and obviate the need for revision surgery in the thick-skinned nose.

Although secondary surgery prior to complete healing is suboptimal, revision surgery within the first year may be preferable in a few rare circumstances. Unlike the otherwise shapely but still-swollen nose for which conservative treatment is appropriate, the overresected or twisted nose that has little hope of spontaneous improvement is sometimes best revised before progressive soft tissue contracture leads to permanent nasal collapse. In these challenging cases, nasal distortion is likely to gradually worsen in the months and years after rhinoplasty due to progressive "shrink wrap" contracture of both the inner and outer epithelial linings. Severely weakened and destabilized skeletal elements subjected to the persistent forces of soft tissue contracture often deform easily, resulting in severe buckling, pinching, retraction, and asymmetry of the cartilaginous framework. And while nonemergent reoperation during the acute phase of postoperative inflammation and edema is generally ill-advised, once the acute changes have passed and the microcirculation has recovered to a reasonable extent, early revision is reasonable—even if a full year has not elapsed—in order to prevent irreversible shrinkage of the nasal skin or mucosa. However, because early revision surgery risks unfavorable wound-healing responses and vascular insufficiency, early reoperation is best reserved for young and healthy individuals with forgiving skin and robust healing tendencies, and not for older patients or those with multiple medical comorbidities. Although the emotionally distressed patient is often seeking early revision, early intervention places additional physiologic stress upon the already damaged nasal tissues, and only the threat of permanent nasal contracture can justify the additional surgical risk. Hence, the decision to intervene early should not be taken lightly, and emotional distress alone is not justification for early surgical revision.

Another scenario in which early revision surgery is preferable is the comparatively minor anatomic deformity presenting in the patient with rapidly healing nasal skin. For the young patient with comparatively thin nasal skin and a smooth healthy complexion, surgical inflammation and swelling often resolve in far less than 12 months. In such patients, persistent skeletal deformities such as a small residual hump may be surgically corrected before the 1-year mark since further delay will not benefit surgical management. In this scenario, expeditious intervention is reasonable since the emotional impact of a flawed outcome can be remedied sooner at negligible increased risk to the patient.

In summary, the 1-year rule is an approximate guideline that is appropriate for some patients and inappropriate for others. And like most aspects of cosmetic nasal surgery, treatment decisions should be made according to the individual physical and psychological needs of the patient, and not according to broad generalizations. For the slow-healing nose, patience is often rewarded with a satisfactory cosmetic outcome in the absence of revision surgery. And while the emotionally distraught patient often pushes for early surgical intervention, sometimes accompanied by anger or hostility, appropriate treatment must not be compromised in the name of expediency. In contrast, early intervention is occasionally justified in the contracture-prone patient who exhibits signs of rapid and severe nasal contracture. However, while early intervention may come as welcome news to these challenging patients, such high-risk cases seldom lead to storybook outcomes and a thorough, candid, and well-documented informed consent is mandatory.

AUGMENTATION GRAFTING OF THE OVERRESECTED NOSE

Perhaps the most common presentation in secondary rhinoplasty is severe structural compromise resulting from overresection of the nasal framework. For most patients, the immediate postoperative deformity is characterized by a partially collapsed and noticeably less attractive nose.

However, the initial deformity often eventually gives way to progressive (delayed) contour deformity as postoperative soft tissue contracture and fibrosis further deform the surgically weakened nasal framework. And while the degree of deformity often correlates to the extent of cartilage resection, noses with soft, pliable nasal cartilage are particularly vulnerable to skeletal overexcision since naturally weak cartilage is already near the threshold for skeletal collapse. Indeed, in the susceptible patient with exceedingly soft cartilage, even modest cartilage excision can lead to severe nasal deformities. Moreover, even when the initial rhinoplasty outcome fails to exceed the threshold for skeletal collapse, age or disease-related deterioration in cartilage strength may eventually lead to failure of the surgically weakened framework and subsequent nasal deformity. Because the severity of soft tissue contracture also varies widely among individuals, those with naturally strong contractile forces—often associated with relatively thin nasal skin—are also at increased risk for delayed skeletal deformities, even when they possess comparatively strong nasal cartilage. Likewise, surgical disruption of vital secondary tip support mechanisms will also predispose to iatrogenic deformity unless secondary support mechanisms are adequately reconstituted or compensated at the time of primary rhinoplasty (4). Noses with preexisting skeletal deviations are also potentially more susceptible to overaggressive excisional techniques since aggressive surgical destabilization may exacerbate underlying imperfections of the nasal cartilage, particularly deviation of the dorsal septum. And while a large nasal tip is often equated with strong nasal cartilage, in reality, wide or bulbous alar cartilages are often exceptionally soft, making them highly susceptible to surgical overresection. Without question, durable and dependable skeletal support is fundamental to a stable and reproducible rhinoplasty outcome, and surgical techniques that imperil long-term structural support are far more susceptible to the powerful and persistent forces of wound healing.

Until recently, "excisional" rhinoplasty techniques have been the workhorse of cosmetic nasal surgery. Traditional methods for reduction of the wide nasal tip and/or rotation of the ptotic tip have relied upon aggressive resection of the lateral crura—the so-called *cephalic trim* technique. Often the cephalic trim is combined with resection of the anterior septal angle, presumably to achieve still greater tip rotation. Sadly, these techniques are more often destructive, rather than constructive, as surgical reduction in skeletal support frequently exceeds the threshold for long-term structural stability. Although excisional techniques may yield acceptable surgical outcomes in select circumstances, the practice of excising vital skeletal tissues to refine the nasal contour is a risky and unpredictable undertaking, and a disproportionate number of adverse rhinoplasty outcomes are probably the result of overaggressive cartilage excision. Indeed, aggressive destabilization of the nasal framework can severely degrade and weaken skeletal support eventually resulting in stigmatic and unsightly deformities of the nasal contour. In fact, even seemingly trivial reductions in structural support can lead to skeletal collapse in the highly predisposed patient. Yet the strong association between excisional techniques and nasal contour deformities has done little to discourage the use of excisional methods as many practitioners still perform and teach only aggressive excisional techniques. Moreover, since both the severity of soft tissue contracture and the threshold for cartilage collapse cannot be reliably determined in advance, and since arbitrary limits for cartilage excision may fail to account for age-related reductions in cartilage strength, the long-term outcome of excisional rhinoplasty is at best haphazard and unpredictable. Fortunately, an improved understanding of nasal tip dynamics and a growing recognition of the harmful effects of overzealous cartilage removal is prompting a gradual shift away from excision-based techniques and toward the adoption of safer and more reliable surgical alternatives. As a result, the unpredictable and somewhat risky practice of aggressive cartilage excision is slowly being supplanted by techniques that conserve nasal cartilage and reliably enhance tip contour with far less risk of skeletal degradation.

OPTIONS FOR SKELETAL TISSUE REPLACEMENT

In the overwhelming majority of revision rhinoplasty cases skeletal support has been severely compromised and damaged or missing skeletal tissues must be surgically reconstituted in order to restore satisfactory nasal contour and function. As a consequence, the skillful and adept use of *autologous tissue grafts* has become the mainstay of revision rhinoplasty. In addition to a familiarity with the biophysical properties and limitations of various graft materials, successful tissue grafting demands a working knowledge of the proper harvest, fabrication, and fixation of each graft material. Although accomplished rhinoplasty surgeons may use specific graft materials differently, the fundamental tenets of graft harvest and application must be followed regardless of the material selected or the specific method of application.

Despite the potential risk of infection, resorption, warping, migration, and other complications associated with autologous graft materials, autografts remain the gold standard in secondary rhinoplasty owing to their *long-term* safety and reliability. However, synthetic implant materials, while controversial, are growing in popularity as an alternative to autologous tissue grafts. In primary augmentation rhinoplasty, porous synthetic polymers, most notably expanded-polytetrafluoroethylene (Gore-Tex, W.L. Gore & Associates Inc., Flagstaff, AZ) and high-density porous polyethylene (Medpor, Porex Surgical Inc., Newnan, GA) have been used successfully for dorsal augmentation with comparatively few initial complications, particularly in comparison to traditional nonporous (silicone) implants (21–24). More recently, the use of porous polyethylene has expanded to include placement in the lower third of the

nose for both functional and cosmetic purposes (25–29). Reported complication rates have generally been low, but delayed infection, extrusion, and foreign body reaction were reported in most series. Somewhat higher complication rates were observed when alloplastic materials were used in revision rhinoplasty, and increased complication rates were attributed to comorbidities such as concomitant septal perforation, prior history of cocaine abuse, cigarette smoking, and other causes of vascular compromise (22,24,30). While alloplastic materials appear to be gaining popularity in primary rhinoplasty, the use of alloplastic materials in revision rhinoplasty remains controversial due to the increased potential for delayed extrusion, infection, and/or foreign body reaction. Consequently, the use of synthetic implant materials in revision rhinoplasty remains comparatively uncommon.

As an alternative to alloplastic materials, some surgeons prefer irradiated rib homografts for complex revision rhinoplasty. While the long-standing debate regarding the longevity and efficacy of irradiated rib grafts continues, recent clinical data suggest that the performance of irradiated rib homografts may be comparable to that of autologous rib tissue (31,32). However, patient objections to cadaveric tissue grafts, the limited availability of human cadaver tissue, the increased costs, and the theoretical potential for the transmission of communicable disease make cadaver cartilage grafts a comparatively seldom-used graft material (33).

While various options such as synthetic polymers and rib homografts are now available to the contemporary revision rhinoplasty surgeon, autologous tissue grafts remain by far the most commonly used reconstructive material in revision rhinoplasty. Owing to their well-defined biomechanical characteristics, lack of toxicity, disease transmission, or foreign body reaction; and their superior long-term safety profile, autologous grafts will likely remain the material of choice for the foreseeable future, and the remainder of this chapter focuses upon autologous graft materials for use in secondary rhinoplasty.

The traditional surgical adage to "replace like with like" is particularly relevant in revision rhinoplasty. Because the nose is a naturally flexible appendage that returns to its initial shape following deformation by facial movement, the reconstructed nose should also remain flexible, yet simultaneously maintain a durable and attractive shape and provide a reliable airway conduit. Of the existing options for replacement of damaged or missing nasal cartilage, only autologous human cartilage approximates the strength, flexibility, thickness, and tolerance to movement of the original nasal tissues. Although autologous bone has previously been advocated for use in nasal reconstruction, the difficulty of harvest, combined with the associated rigidity, bulk, and susceptibility to absorption, makes bone a less commonly used option for most secondary rhinoplasty applications (3,34,35).

Owing to a wide variation in nasal morphology, particularly in the secondary rhinoplasty patient population, and the widely differing biomechanical and physical requirements within various regions of the nose, no single graft material meets all of the reconstructive requirements for every revision rhinoplasty patient. Moreover, autologous cartilage graft materials are all limited in supply, and restricted to the surplus portions of the quadrangular septum, the conchal region of the external ear, and the cartilaginous rib cage. Consequently, the choice of autologous graft materials will vary from patient to patient according to the location, size, and shape of the nasal defect, as well as the availability of cartilage from a particular donor site, the preference of the surgeon, and the willingness of the patient to authorize graft harvest. In some cases, a single graft material may enable a satisfactory surgical outcome, whereas in more complicated revision cases more than one graft type may be needed for the best reconstructive result. In the case of exceedingly large skeletal defects or the multiply-revised patient with prior depletion of both septal and conchal cartilage donor sites, rib cartilage becomes the only viable treatment option. Regardless of the graft materials chosen, the skillful application of autologous tissue grafts remains the foundation of contemporary revision rhinoplasty, and a sound working knowledge of each graft type is essential for any revision surgeon.

Septal Cartilage

Perhaps the autograft best suited to revision rhinoplasty is septal cartilage. Histologically, septal cartilage is classified as hyaline cartilage—a semisolid matrix of chondroitin sulfate embedded with chondrocytes and a network of type II collagen fibers (36,37). Scanning electron microscopy reveals a mesh-like framework of large collagen fibers yielding additional strength relative to the loosely organized and smaller collagen fibers seen in lower lateral cartilage (36). The thickness of septal cartilage also varies according to the anatomic site and ranges from 0.74 to 3.03 mm (38). Thinner portions of the nasal septum correspond closely to the 0.7-mm average thickness of the lateral crus (39,40), making septal cartilage uniquely well suited to reconstruction of the thin and lightweight lower lateral cartilages. Although the least abundant of all autologous cartilage graft materials, septal cartilage has numerous advantages over other sources of autologous tissue, including its proximity to the surgical field and its nose-like biophysical properties. Harvest of cartilage from a healthy nasal septum is generally quick and uncomplicated, but care must be taken to preserve an outer perimeter of residual cartilage to maintain structural support—the so-called septal "L-strut". Minimum width of the L-strut remains a matter of controversy and should probably be kept as wide as possible, but a 1.0-cm-wide L-strut is generally considered adequate for most noses (3). Despite preservation of a 1.0-cm L-strut, a sizeable piece of septal cartilage can still be harvested from most leptorrhine noses (Fig. 184.4A–D). Graft harvest is typically more difficult in noses with preexisting septal deformities resulting from growth disturbances,

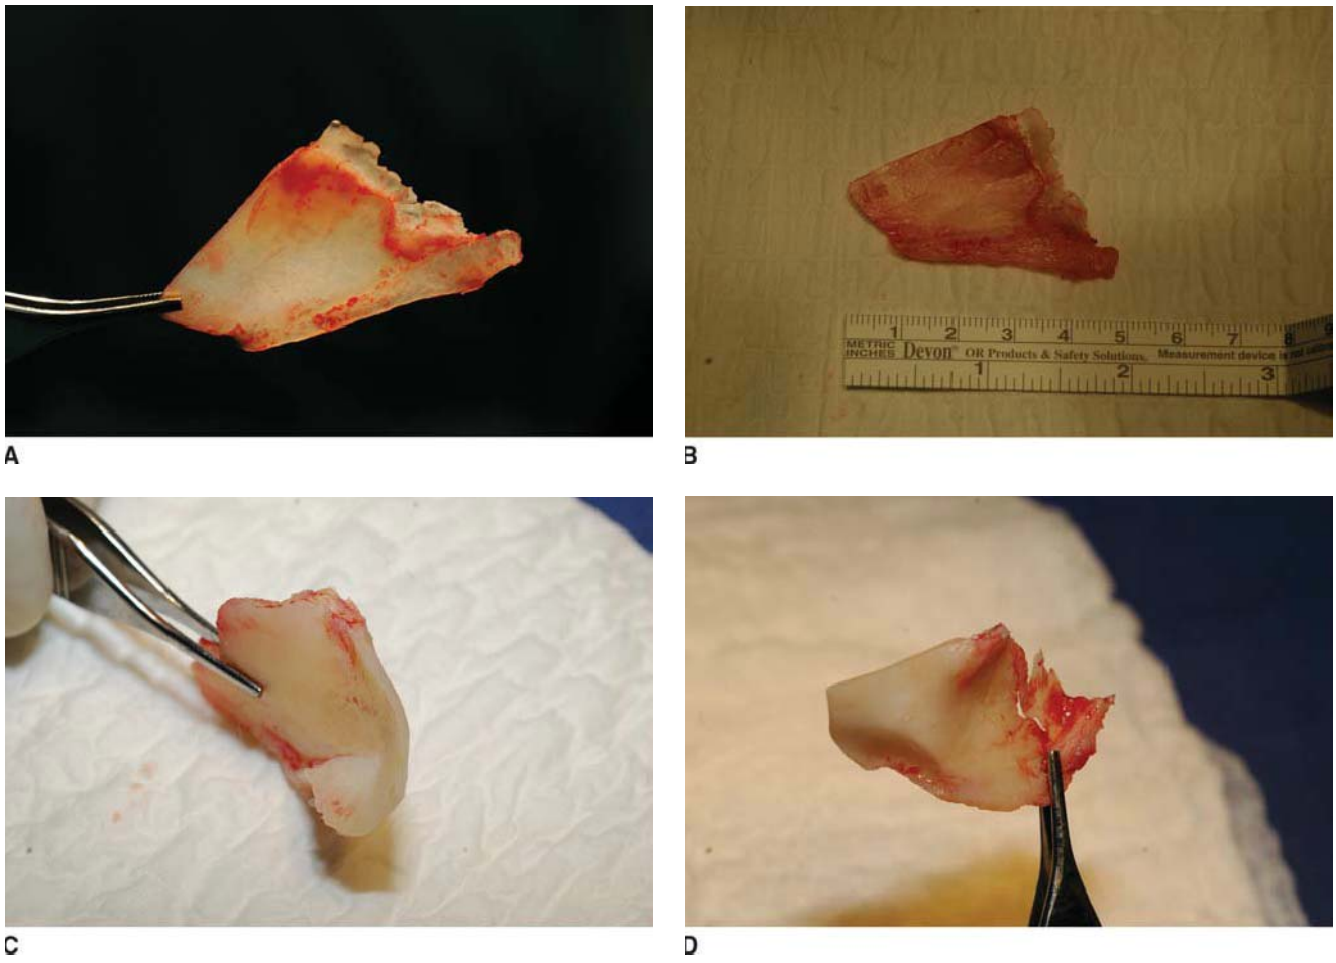

Figure 184.4 Septal cartilage graft material. **A:** Septal graft material harvested with L-strut preservation, **(B)** typical graft dimensions in the leptorrhine nose, and **(C,D)** donor graft material distorted by preexisting septal deformity.

nasal trauma, and/or prior nasal surgery, but elimination of these deformities often contributes to improved airway function. Graft yields may vary according to patient ethnicity and age (41), with larger yields in younger patients due to forward expansion of the bony ethmoid plate over time. Interestingly, graft size may not correlate with size of the external nose, making it difficult to predict the availability of septal graft material in advance (42).

Historically, septal cartilage has been regarded as a resilient graft material and is seldom associated with absorption, infection, warping, or extrusion (3,33). Owing to its combination of axial rigidity and transverse flexibility, septal cartilage is commonly used in secondary rhinoplasty for structural grafting; including struts, battens, extension grafts, spreader grafts, and various tip grafts. Similarly, because of its stability and relative ease of carving, septal cartilage can also be sculpted to create a wide variety of surface (onlay) grafts for camouflage or contour augmentation. Lightly morselized ("crushed") septal cartilage grafts can also be used for augmentation, smoothing, or camouflage with minimal risk of edge prominence or graft resorption (43).

However, like all donor tissues, septal cartilage has limitations. While convenient, harvesting septal cartilage leads to additional soft tissue trauma thereby exacerbating nasal inflammation and edema, and potentially compromising tissue perfusion. Moreover, although septal cartilage is preferred for its biomechanical properties, adequate amounts of surplus septal cartilage are not always available. In primary rhinoplasty, many flat underprojected noses lack adequate septal cartilage for significant grafting needs, and in revision cases surplus septal cartilage may be damaged or depleted from previous surgery. Efforts to generate large amounts of tissue-engineered human septal cartilage with biomechanical properties equivalent to natural septum are under way, but to date bioengineered septal cartilage is not yet clinically available (37). Interestingly, the adult human nasal septum is the preferred donor tissue for laboratory-engineered cartilage since septal chondrocytes demonstrate a greater proliferative effect in monolayer culture—a crucial preliminary step in cell culture—and they also demonstrate a better overall proliferative and chondrogenic potential relative to most other cartilage cell types (44).

Conchal Cartilage

Elastic (or hyaline-elastic) cartilage harvested from the conchal bowl of the external ear is another commonly used source of autologous cartilage. Histologically, auricular cartilage contains both type I and type II collagen and elastic fibers (37). Unlike septal cartilage that typically yields a flat uniform specimen, conchal cartilage is cupped, generally thicker, and more prone to cracking with manipulation. Moreover, conchal cartilage must be harvested from a separate and distinct surgical site, adding to surgical morbidity and time utilization. However, a single piece of conchal cartilage can be obtained from the typical ear measuring approximately 2.4 × 2.4 cm (45) (Fig. 184.5). Harvest can be performed through either an antihelical fold incision or a postauricular crease incision with minimal cutaneous scarring. When needed, harvest may also include the posterior conchal perichondrium, which can be used for tip graft camouflage or augmentation of thin nasal skin. In order to prevent postoperative auricular contour deformities following harvest of the entire conchal bowl, the antihelical fold must be fully preserved and a bolster-type dressing is required to maintain conchal contour during initial healing. Risks of conchal graft harvest include skin necrosis, scar contracture, infection, or hematoma, but these problems are exceptionally rare in experienced hands.

Figure 184.5 Conchal cartilage graft material harvested from the postauricular approach. Note undersurface of the conchal skin after contiguous excision of the concha cymba and cavum.

Like septal cartilage, conchal cartilage grafts are remarkably resilient and seldom succumb to infection, absorption, or extrusion making them a popular graft option in nasal surgery (3,31,45). However, conchal grafts are notoriously difficult to conceal probably as a consequence of their nonuniform shape, and warping or edge prominence are common complications with superficial placement, particularly in the absence of secure suture fixation. Moreover, beveling of graft edges on the outer surface may actually exacerbate graft edge prominence. Owing to its natural bulk and curvature, and its corresponding thickness and lack of axial rigidity, conchal cartilage is also poorly suited to the fabrication of columellar struts and septal extension grafts (SEGs). In such applications, double-layered grafts are often needed to achieve a strong and reasonably straight structural element. However, the natural graft curvature of ear cartilage is sometimes an asset in the fabrication of tip grafts, butterfly grafts, alar rim grafts, or other applications that require a gently curved surface contour (45). Placement of conchal grafts in direct contact with the dermis is ill-advised since graft prominence is common and since tenacious adherence to the skin makes removal exceedingly difficult.

In addition to standard conchal cartilage grafts, *composite* chondrocutaneous grafts are also occasionally useful in secondary rhinoplasty. Composite grafts are most commonly used to correct severe retraction of the alar rim or columella following overresection of the lateral crus or caudal septum, respectively (46,47). Small (5 × 15 mm) composite grafts can be harvested from the concha cavum while still permitting primary closure of the donor defect after undermining of the adjacent skin. Although thick, these grafts are often indispensible in correcting the aforementioned secondary nasal deformities since they replace missing vestibular skin and augment deficient skeletal support.

Costal (Rib) Cartilage

Costal cartilage is another form of hyaline cartilage containing a mix of type I and type II collagen that is mechanically stronger than either septal or conchal cartilage (37). Moreover, unlike conchal or septal cartilage, costal (rib) cartilage is also available in relative abundance. Consequently, rib cartilage is often the material of choice when large volumes of cartilage are required, or when septal or conchal donor sites have been depleted from prior surgery. However, the harvest of rib cartilage is considerably more invasive and time-consuming. Potential risks of rib graft harvest include pneumothorax, chest wall deformity, infection, hematoma/seroma, and/or intense postoperative pain. Harvest from the right chest wall is preferred to avoid inadvertent injury to the underlying left-sided cardiac tissues, and a 3.0-cm chest-wall incision typically affords adequate exposure while limiting donor site scarring. In women, an inframammary crease

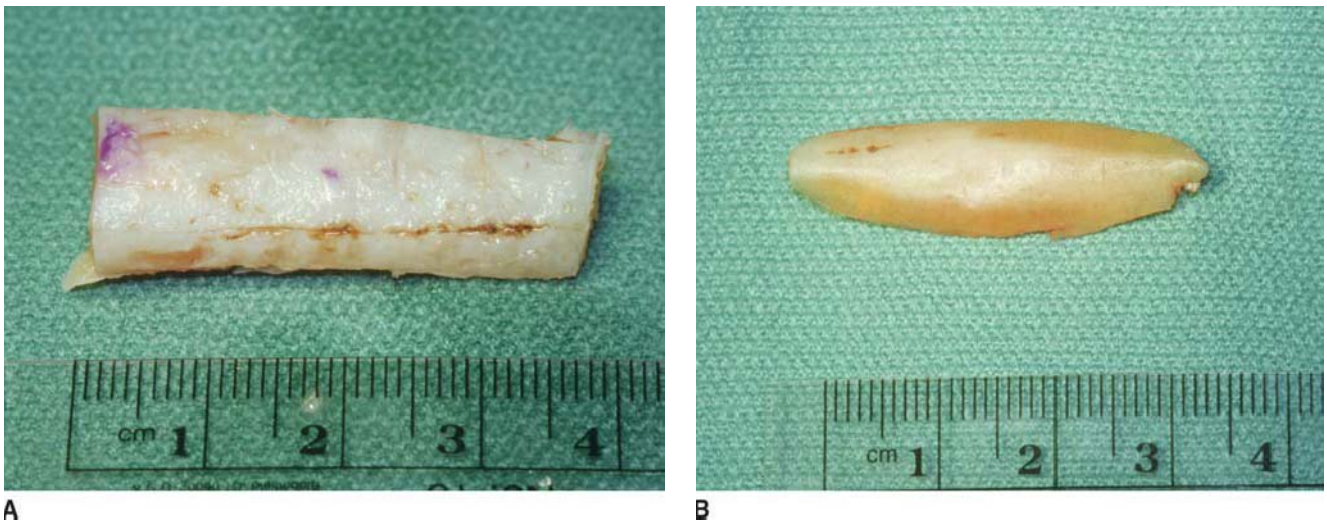
incision permits concealment of the scar beneath the bikini line but restricts access to the fifth, sixth, or possibly seventh ribs. Obese patients may require a longer incision for better visualization due to extra subcutaneous fat, and in older patients ossification of the rib cartilage may make harvesting and/or carving of the graft difficult (48). However, significant ossification can also occasionally occur in younger patients. The author has harvested rib on two occasions in patients less than 30 years of age who were both found to have near-complete ossification of the rib cage (*personal observation*). In one patient, this was attributed to a rare manifestation of Addison disease, while no known etiology was found for the other patient. Postoperative discomfort from rib harvest can be minimized with blunt spreading of the overlying rectus muscle, and grafts may be harvested as partial or full-thickness specimens with or without the attached perichondrium (Fig. 184.6A and B). Acute postoperative pain is greatly diminished with placement of a percutaneous bupivacaine infusion pump allowing for 4 to 5 days of postoperative donor site numbness.

While rib cartilage is available in abundance, costal cartilage has a strong propensity for warping (3,33–35,44,48–50). Soaking of the specimen in saline followed by concentric carving of the graft may help to minimize warping (51), but aggressive thinning of the graft may contribute to structural instability and eventual warping despite preventative measures. Moreover, experimental evidence suggests that saline-moistened costal grafts may continue warping for up to 4 weeks postharvest (49). Even thick dorsal onlay grafts can warp and/or migrate when the graft fails to adhere or when the graft/host interface is not sufficiently reciprocal. Some experienced rib graft surgeons feel that fixation of dorsal onlay grafts with perichondrium may help to minimize postoperative warping and migration.

In an attempt to further prevent warping of dorsal rib onlay grafts, various modifications have been advocated. Internal stabilization of costal cartilage by longitudinally skewering the graft with a Kirschner wire (K-wire) offers resistance to warping at the expense of a permanent foreign body (50). The use of a *composite* osseocartilaginous dorsal augmentation graft harvested from the sixth, seventh, or eleventh rib allows for osseointegration of the bony component to the bony substructure, promoting stabilization of the graft against migration and/or warping (34,35). Alternatively, rib cartilage may also be "diced" into 0.5- to 1.0-mm cubes and encased in a sleeve of temporalis fascia to create a malleable dorsal augmentation graft that is highly resistant to warping (52,53). The so-called diced cartilage–fascia (DC-F) graft may be used for partial or complete dorsal augmentation depending upon graft size and positioning. DC-F grafts may also be constructed from conchal or septal cartilage, but donor quantities may be insufficient for large volume defects. The harvest of temporalis fascia is generally uncomplicated and associated with minimal donor site morbidity, and the DC-F graft has proven both effective and reliable without warping or clinically significant absorption in long-term clinical application (52,53).

Soft Tissue Grafts

Although skeletal restoration is the foundation of revision rhinoplasty, thickness and uniformity of the overlying nasal skin also plays a critical role in secondary nasal surgery. Nasal skin at the extremes of thickness—extremely thick skin or exceedingly thin nasal skin—often present the greatest technical challenge in secondary rhinoplasty. For noses with extremely thick nasal skin, excessive soft tissue bulk completely obscures the skeletal contours necessary for a well-defined and attractive surface topography.



A B

Figure 184.6 Rib cartilage graft material. **A:** Specimen of sixth rib following removal of perichondrium, and **(B)** solid dorsal onlay graft contoured from sixth rib specimen.

In contrast, naturally thin nasal skin provides little if any camouflage, and even minor skeletal imperfections are easily discernible beneath the ultrathin soft tissues. In the multiply operated nose with overly thin skin, surgically induced atrophy can also lead to additional thinning and still greater cosmetic deformity (Fig. 184.7A–C). Ironically, atrophic thinning is often most severe over the rhinion and nasal tip where skeletal imperfections most commonly arise. Thin-skinned patients are also more susceptible to surgically induced erythema, which may become progressively longer lasting with each successive surgery and which may eventually fail to resolve altogether. In addition to the

drawbacks of naturally thin nasal skin, unsightly contour irregularities can also develop in patients with intermediate nasal skin thickness as a consequence of localized surgical injury and subsequent (focal) skin atrophy. When severe, random inconsistencies in skin thickness can produce an unsightly lumpy appearance despite a smooth underlying skeletal substructure. Moreover, attempting to eliminate these surface irregularities through alteration of the underlying skeletal framework may prove exceedingly difficult and may even jeopardize skeletal integrity.

Treatment of overly thin nasal skin or focal skin inconsistencies is often best achieved using autologous soft tissue augmentation grafts. Various autologous materials have been used to augment skin thickness including dermis, perichondrium, superficial musculoaponeurosis (SMAS), and temporalis fascia. De-epithelialized dermis may be harvested from the abdomen using previous surgical scars (e.g., C-section, appendectomy) or from an elliptical Pfannenstiel-type incision below the bikini line (54) (Fig. 184.7B and C). Modest amounts of perichondrium can be obtained from the posterior conchal bowl, whereas larger amounts can be obtained from costal cartilage. A 4.0 × 5.0 cm sheet of temporalis fascia is easily obtained via a 2.0-cm temporal scalp incision placed over the midtemporalis muscle. The nasal SMAS layer, a fibromuscular tissue layer that lies immediately deep to the subdermal fat, may be excised *en bloc* from beneath the nasal skin flap to improve tip contour, definition, and skin elasticity (55). Nasal SMAS should only be harvested from patients with exceptionally thick nasal skin and harvest is generally confined to the supratip and adjacent sidewalls where the SMAS layer is often thickest. Once removed, excised material can be reimplanted in other areas of the nose for contour enhancement (e.g., radix, rhinion, or sidewall augmentation) or for focal augmentation in areas of excessive skin thinning. Survival of autologous SMAS grafts is generally favorable in the absence of preexisting vascular insufficiency.

Since soft tissue graft survival is dependent upon an adequate recipient-site blood supply, autologous soft tissue grafts may succumb to resorption in patients with vascular insufficiency such as smokers, diabetics, or those with previously devascularized skin. While no autologous soft tissue graft is completely immune to resorption, soft tissue graft survival is generally favorable in healthy patients, especially when applied in a single layer to optimize surface contact with the recipient tissue bed. Blanketing the outer surface of the nasal framework with a single layer of autologous soft tissue can also smooth minor indentations, camouflage rough surfaces, and eliminate minor edge prominence of cartilage onlay grafts, thereby obviating the need for difficult alterations in skeletal contour. When performing either primary or revision rhinoplasty, all soft tissues removed in the course of surgical dissection should be retained in saline for possible reimplantation later in the case.

EXTERNAL RHINOPLASTY APPROACH

Surgical exposure for secondary rhinoplasty can be achieved via either the external or the endonasal rhinoplasty approach. For minor revision procedures, the endonasal (or "closed") approach is often preferable, offering minimal tissue disruption with less swelling and inflammation, and a faster return to normalcy. However, the endonasal rhinoplasty approach also restricts visibility, limits suture fixation of graft tissue, and hampers *en bloc* excision of scar tissue from beneath the nasal skin flap. Consequently, despite the requirement for a visible columellar incision, the wide-field surgical exposure afforded by the external (or "open") rhinoplasty approach is generally preferred for complex secondary rhinoplasty. The additional exposure and visibility afforded by the external rhinoplasty approach offers greater surgical exposure, increased diagnostic accuracy, and greater ease of suture graft fixation, all while preserving an intact vascularized epithelial barrier between the surgical field and the nasal cavity. Since a carefully repaired transcolumellar incision seldom creates an objectionable scar, and since various surgical techniques are precluded with the endonasal approach, external rhinoplasty is generally the procedure of choice for complex revision nasal surgery.

In the severely misshapen and previously operated nose, normal anatomic landmarks are often heavily distorted making subsequent incision placement difficult. Moreover, what may seem like appropriate incision placement at the onset of secondary surgery may later result in unfavorable scar positioning following skeletal augmentation and subsequent redraping of nasal skin. Consequently, additional care must be taken to anticipate the possible migration of incision lines and to locate the transcolumellar and marginal incisions as close to their correct (original) anatomic location as possible. Although the presence of nonanatomic cartilage grafts may make locating the lateral crural cartilage remnants difficult, marginal incisions should follow the caudal border of the lateral crus to avoid unnecessary scar visibility.

In the previously operated nose with a conspicuous transcolumellar scar, design and placement of the subsequent columellar incision can become an issue. Although the goal of surgically eliminating an unsightly columellar scar with scar excision is laudable, skin excision should be avoided unless copious skin redundancy will ensure a tensionless closure *after* skeletal re-expansion is complete. Ironically, skeletal re-expansion will often stretch the columellar skin and minimize visibility of the existing scar. Moreover, the author has found that reusing an unsightly midcolumellar scar for placement of the subsequent incision can often dramatically improve scar appearance when closed with carefully everted skin edges. Alternatively, when placing the columellar incision in previously *unoperated* columellar skin, the incision should be located over the columellar

double-break—approximately halfway up the columella. In addition to providing a narrow segment and thus a shorter scar, this location is also partially concealed by the junction of two aesthetic nasal subunits. Finally, use of the traditional five-cornered "inverted-V" incision offers additional scar camouflage similar to a geometric broken line–type scar concealment, and optimizes flap alignment with an additional reference point relative to the alternative stair-step incision.

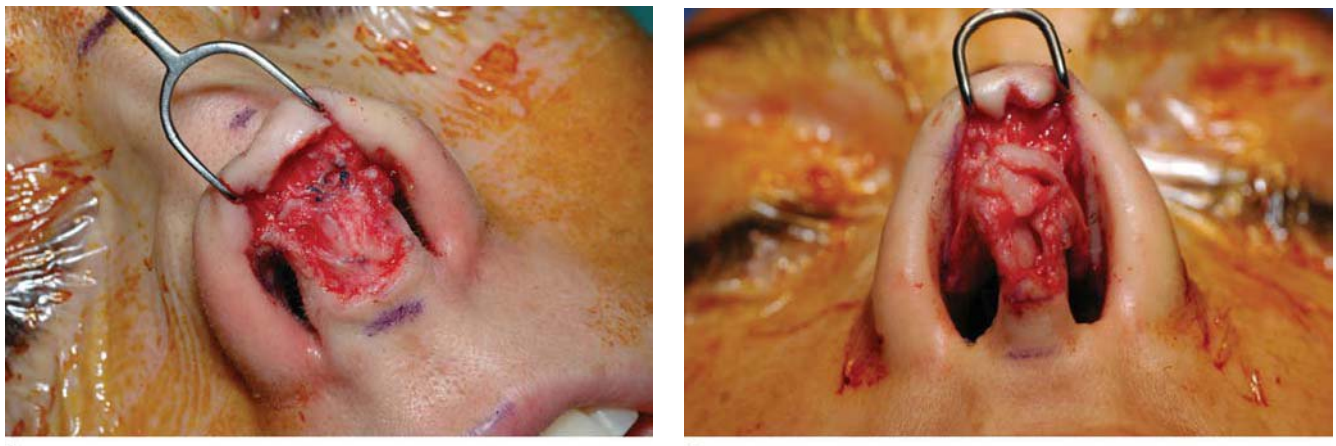
SOFT TISSUE SURGICAL TECHNIQUE

Meticulous and gentle soft tissue technique is essential in any rhinoplasty, but especially in revision rhinoplasty where nasal tissues are already partially compromised by varying degrees of scar and vascular insufficiency. Avoiding the use of crushing forceps, prolonged or aggressive tissue retraction, excessive tissue desiccation, or overzealous use of electrocautery will minimize soft tissue trauma and limit the release of harmful inflammatory mediators. While atraumatic soft tissue technique is recommended for all revision rhinoplasty patients, it is particularly important in noses with scar-prone skin or substantial vascular compromise, since aggressive tissue handling may trigger adverse wound-healing responses and ruin an otherwise successful reconstruction. Moreover, the survival of all free tissue grafts, the prevention of postoperative infection, and the viability of any surgically manipulated tissue is dependent upon an adequate and uninterrupted nutrient blood flow. While all patients suffer some degree of soft tissue swelling and inflammation, gentle soft tissue technique can mitigate surgical inflammation, minimize lymphedema, and optimize soft tissue perfusion—often determining the difference between a mediocre surgical outcome and a surprisingly good cosmetic result.

SURGICAL DECONSTRUCTION OF THE PREVIOUSLY-OPERATED NOSE

Perhaps one of the greatest technical challenges in secondary rhinoplasty is surgical *deconstruction* of the badly damaged nose. Deconstruction is the first step in dismantling and exposing the deformed, malpositioned, and/or damaged nasal components prior to surgical reconstruction. As a consequence of exposing the misshapen nasal framework, deconstruction also greatly enhances diagnostic accuracy and frequently leads to critical refinements in the surgical game plan. However, deconstruction is typically a difficult undertaking in the previously operated nose, and liberating the malpositioned and/or damaged cartilage remnants without causing further harm can prove extremely challenging in some patients (Fig. 184.8A and B). At the very least, the task of elevating the nasal skin envelope and exposing fragile cartilage remnants embedded in scar tissue, all while avoiding injury to the surrounding nasal lining, is a time-consuming endeavor that requires considerable patience and skill. Slow and tedious dissection with heavy reliance upon blunt technique is often necessary to safely deglove the weakened and distorted nasal framework.

During the course of deconstruction, skeletal remnants are often observed to have migrated from their intended position or to have transformed from their desired shape—both an unwanted consequence of scar contracture. Surgically induced contracture of the nasal lining not only leads to malpositioned and misshapen skeletal remnants, it may also result in mucosal adhesions and cartilage fixation, further adding to the difficulty of surgical deconstruction. Hence, deconstruction often involves lysis of scar adhesions to release the entrapped skeletal remnants and to permit appropriate repositioning of the displaced cartilage components.



A B

Figure 184.8 Examples of severe tip cartilage distortion resulting from previous cosmetic rhinoplasty. **A:** Scarred and fragmented tip cartilages prior to deconstruction, and **(B)** telescoping collapse of overresected tip cartilages prior to deconstruction.

Perhaps the most common example of contracture-mediated cartilage distortion is *retraction of the alar rim*. Alar retraction is an unsightly nasal deformity often resulting from overexcision of the lateral crus during reduction rhinoplasty. When overexcision of the cephalic crural border leaves a crural remnant that is too weak to resist deformation by scar contracture, the weakened lateral crus and the attached alar soft tissues both retract cephalically, producing a conspicuous and unsightly notching of the nostril (Fig. 184.2B). Aggressive surgical excision of the cephalic lateral crus is the basis of the *cephalic trim* maneuver, a traditional but haphazard tip refinement technique still in widespread use today. The severity of nostril retraction is largely determined by the extent of cartilage resection, since a large skeletal void is associated with both greater scar contracture and greater structural compromise. And despite the strong association of the cephalic trim maneuver with unsightly surgical tip deformities, overexcision of the cephalic margin is an almost universal intraoperative finding in most complex revision rhinoplasty cases. While successful restoration of the damaged crural cartilage is usually possible, it is frequently difficult or impossible to surgically unfurl the contractured and foreshortened epithelial lining. And in cases of irreversible scar contracture, composite (chondrocutaneous) grafts are necessary to replace the missing vestibular epithelium and to buttress the alar margin against recurrent retraction.

Despite the painstaking nature of surgical deconstruction, the time spent properly dismantling the nose is well worth the investment. Only through a methodical deconstruction are the skeletal and soft tissue components fully exposed, mobilized, and evaluated in preparation for surgical reconstruction. However, during the course of deconstruction, a number of critical decisions must be made. First, the surgeon must decide whether or not to retain the severely damaged nasal cartilages. In theory, the use of cartilage grafts to augment or replace damaged skeletal tissues can restore structural integrity and produce considerable functional and cosmetic enhancements. However, as the scope of deconstruction and replacement grafting expands, so too does the probability of unforeseen healing aberrations related to surgical inflammation and failed revascularization. Skeletal distortion resulting from graft resorption, scarring, contracture, or infection may taint the final outcome considerably, and the excessive use of graft material can also lead to a whole host of new problems. And since a shapely, rigid, and sturdy neoframework is required for predictable healing, the amount and quality of the available replacement tissue also has a profound bearing upon this decision. Because appropriate replacement tissue is sometimes in short supply, strategic intraoperative planning is also necessary to utilize limited resources wisely and to their best overall advantage. For this reason, it is generally preferable to deconstruct all problem areas of the nose first, before removing existing skeletal elements and allocating replacement tissues. However, when the existing skeletal elements cannot be salvaged by either reshaping or repositioning, autologous cartilage grafts become the primary workhorse for strengthening, reinforcing, or sometimes completely replacing damaged skeletal components. While replacing or reinforcing critical structural elements with cartilage grafts will always have inherent risks, in the healthy individual with ample donor tissue and a robust recipient blood supply, the cosmetic and functional benefits of *structural* cartilage grafting usually *far surpass* any other surgical strategy.

In addition to damaged native nasal tissues, many complex revision rhinoplasty patients also present with previously placed tissue grafts or implants that may be contributing to unwanted functional and/or cosmetic deformities. A variety of options for treating unsightly grafts or implants are available to the revision surgeon including *in situ* modification by shaving or repositioning, camouflage, substitution, removal, or combinations therein. As part of the deconstruction process, the decision whether or not to retain these previously placed materials must take into account the overall risk-to-benefit ratio and the availability of suitable replacement materials. However, not all previously placed cartilage grafts should be discarded *per se*. Misshapen or malpositioned grafts that have no detrimental *external* cosmetic impact are often best left alone since removal may lead to unwanted external contour deformities. Moreover, contour deformities resulting from graft removal are sometimes a consequence of scarring and thickness irregularities of the nasal skin flap that are frequently very difficult to eliminate. And while the removal of unsightly skeletal components may be cosmetically justified, aggressive deconstruction of the nasal framework can also lead to significant structural instability, potentially opening the door for catastrophic consequences if the nasal soft tissues are pushed beyond their limits. In the severely ravaged nose, soft tissue linings provide both vascular and *structural* support, serving to compensate for severely weakened skeletal components. The result is sometimes a structurally borderline, yet deceptively healthy-looking appendage that belies its fragile and tenuous state. Unless the aggregate soft tissues have sufficient vascular integrity to support skeletal replacement grafts *and* to tolerate the additional stresses associated with aggressive surgical deconstruction, a far more conservative approach must be adopted intraoperatively to prevent potentially catastrophic consequences. Moreover, even in the generally healthy nose, aggressive deconstruction of the nasal framework results in progressive structural destabilization and vascular disruption, adding an element of unpredictability to the surgical outcome as the nose becomes increasingly vulnerable to the vagaries of wound healing. Hence, aggressive deconstruction is often a necessary evil, but one that is justified only when the potential benefits are likely to exceed the associated individual

risks. Moreover, during surgery, the prudent surgeon will continually reassess the nasal soft tissues for telltale signs of surgical intolerance and will quickly alter the treatment plan as conditions dictate.

Another key decision confronting the revision surgeon is how large to make the neo-skeletal framework. Ideally, this decision is made early in the course of skeletal deconstruction before irreversible alterations to the existing skeletal framework are undertaken. For the overresected nose, the cosmetic ideal typically requires substantial skeletal enlargement, but the surgeon must weigh the cosmetic benefits of a larger and more attractive nasal framework against the potential hazards of an overly taut soft tissue envelope. Assessing the quality and mobility of the soft tissue envelope *prior* to surgery is paramount since noncompliant skin greatly limits skeletal re-expansion. While placing healthy elastic skin on stretch can enhance tip definition and lead to significant tip refinement, placing fibrotic inelastic skin under sufficient tension to improve surface contour may potentially impair tissue perfusion and lead to ischemic compromise (20). Consequently, patients with severely foreshortened noses coupled with severely noncompliant skin are best deferred unless skin-stretching exercises can adequately improve soft tissue elasticity. Moreover, in patients with thick inelastic skin and weak nasal cartilage, achieving a skeletal framework of sufficient strength to stretch the noncompliant skin envelope can also prove extremely challenging. In fact, the combination of thick fibrotic skin and weak central tip support is among the most challenging of all revision noses (20). In most cases, rib cartilage grafts become the only reliable means of creating a neo-framework of sufficient strength and rigidity to forcefully stretch, and subsequently thin, the dense fibrotic nasal skin. However, because long slender rib grafts under compressive load are more prone to warping, rib grafts are generally fabricated much thicker than would be cosmetically ideal. On the other hand, assuming cosmetic tolerances will permit a wider nose, the surgically distended skin produced by rib grafting often results in a more elegant and better-defined nasal contour. Nevertheless, due to the increased structural loads carried by the newly fabricated skeletal framework, coupled with the corresponding increase in tension placed upon the overlying skin, the risks of inadequate skin perfusion and/or skeletal deformation are markedly increased with this aggressive treatment strategy (20). And depending upon the extent of closing tension, the amount of postoperative swelling, and the reliability of the microcirculation, vascular insufficiency can develop even in young healthy patients. While frank skin necrosis is exceedingly rare, underperfused tissues can lead to graft resorption, wound infection, or wound dehiscence, and extreme care must be taken to minimize vascular insults when augmenting the overresected nose. Moreover, a wide and masculine nasal contour is sometimes unavoidable when using rib cartilage grafts to expand the severely foreshortened nose, and despite the improved profile contour, significant width increases may occasionally result in patient dissatisfaction.

In the event that thick and surgically scarred nasal skin fails to accommodate optimal skeletal enlargement, judicious surgical debulking of the subcutaneous tissues can sometimes improve both skin compliance and surface definition (20,55). In histologic studies of the thick-skinned nose, Garramone et al. (56) observed that extra skin thickness is derived mostly from hypertrophy of the fibromuscular tissue layer found just beneath the subdermal fat. When scarred and thickened from prior surgery, this tissue layer can greatly inhibit skin elasticity. Because the thickened fibromuscular tissue layer—also known as the nasal SMAS (57)—can be carefully excised from the nasal tip and supratip without damaging the subdermal plexus, debulking of the nasal SMAS can greatly reduce skin thickness while simultaneously improving both skin distensibility and surface contour (55).

However, in the surgically scarred nose, SMAS excision is a potentially high-risk maneuver that may potentially reduce skin flap perfusion in a nose that may already be on the verge of vascular insufficiency. While SMAS debulking is often performed safely in revision rhinoplasty patients, previous surgical scarring may make navigation far more challenging, and the added exposure of the external rhinoplasty approach is crucial. Possible complications such as inadvertent skin perforation or ischemic skin necrosis are rare, but these risks are increased in the severely fibrotic nose with prior circulatory compromise. Hence SMAS excision should be reserved only for patients with a robust cutaneous circulation and exceedingly thick, but otherwise healthy nasal skin. In patients with nasal skin thickness of at least 5 mm, careful SMAS excision can be performed in areas where improved distensibility and surface definition are desired—usually the tip, supratip, and supra-alar sidewalls. In order to maintain a uniform flap thickness and avoid injury to the subdermal plexus, the fibromuscular SMAS layer is excised *en bloc* under direct visualization using mostly blunt dissection (55) (Fig. 184.9A–C). With careful separation of the SMAS layer, the subdermal plexus is left largely undisturbed, and the nutrient blood supply to the nasal skin is protected—a vitally important step, especially if aggressive skin stretching is also planned. However, special care must be exercised near the alar groove where the primary source of cutaneous blood supply—the lateral nasal artery—has been shown to enter the subdermal plexus (58).

In contrast to re-expansion of the undersized nose, revision of the *oversized* nose presents an entirely different set of surgical issues. While *reduction* rhinoplasty is often quite challenging in its own right, the potential for catastrophic vascular insufficiency is comparatively small since redundant nasal skin is usually generated from skeletal downsizing. As long as the redundant skin envelope shrinks promptly and adheres tightly to the smaller and more attractive skeletal framework, fibrosis of the subcutaneous

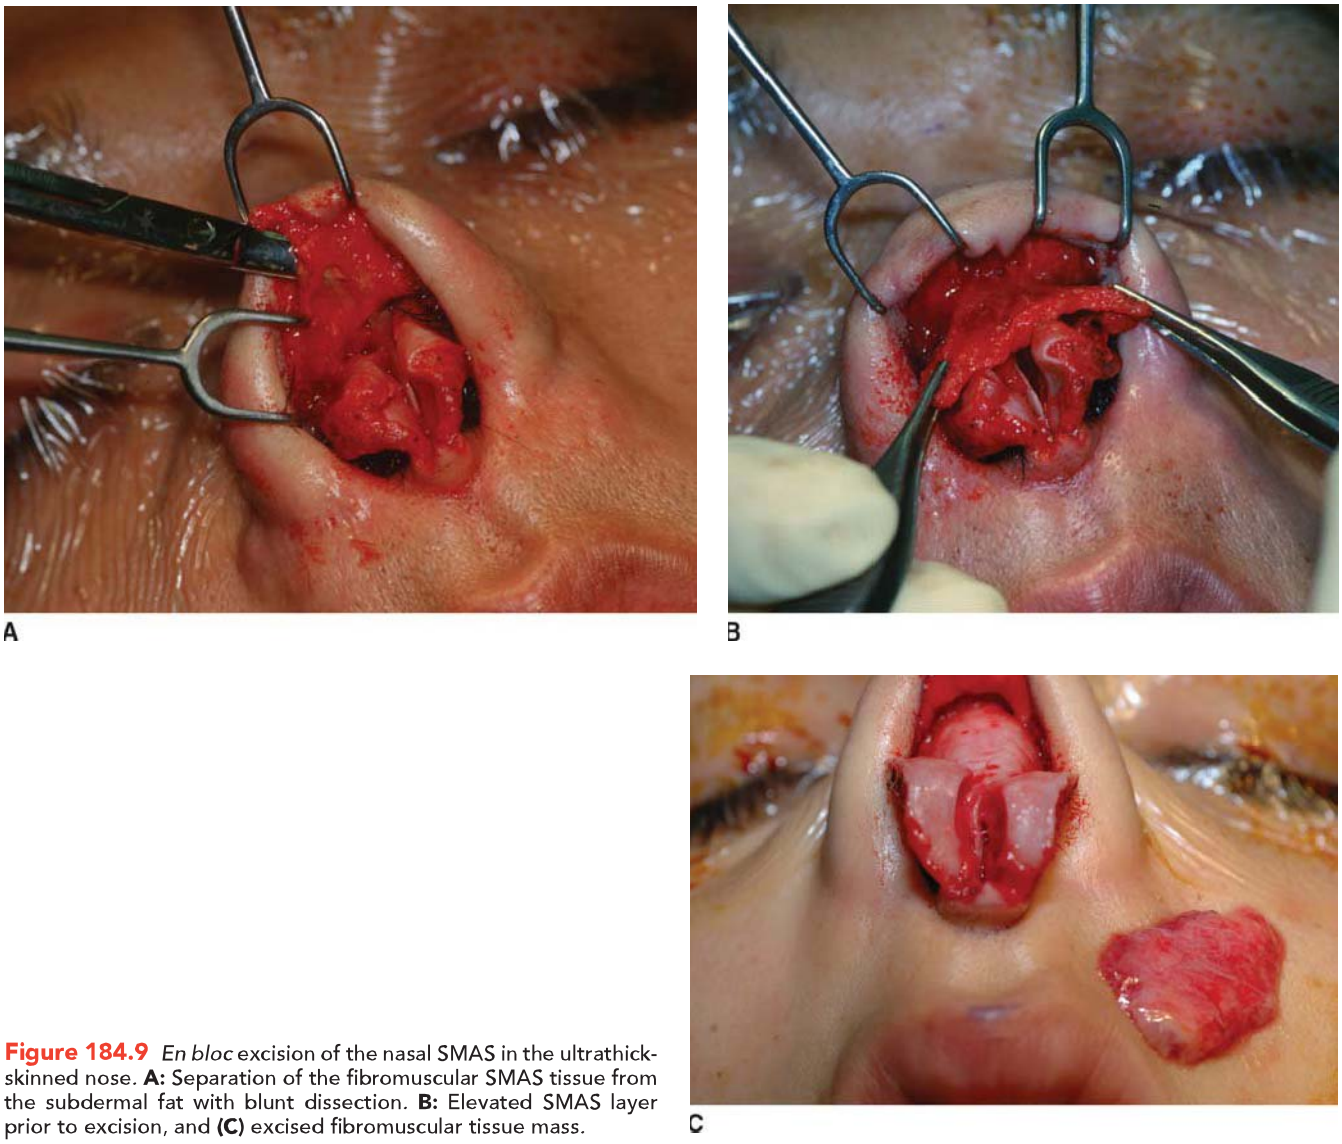


Figure 184.9 *En bloc* excision of the nasal SMAS in the ultrathick-skinned nose. **A:** Separation of the fibromuscular SMAS tissue from the subdermal fat with blunt dissection. **B:** Elevated SMAS layer prior to excision, and **(C)** excised fibromuscular tissue mass.

tissues is avoided and a well-defined and more attractive nasal contour typically ensues (see Case One). Avoiding circumstances that aggravate or prolong postoperative edema is particularly important in this patient population, since the large dead space predisposes to the formation of chronic lymphedema and subcutaneous fibrosis. In fact, the overly large nose covered with thick sebaceous nasal skin is highly susceptible to the development of dead space fibrosis, and the surgical outcome in this scenario is often a smaller, yet still unattractive nose. Consequently, it is generally preferable to avoid dramatic nasal size reductions in the oversized nose with thick, fibrotic nasal skin. Although conservative size reductions may produce a nose that is still too large for an ideal cosmetic outcome, a better-proportioned and well-defined (if still somewhat large) nose is infinitely preferable to a small, amorphous, and unattractive one.

RECONSTRUCTION OF THE SURGICALLY DEVASTATED NASAL TIP

Central Tip Support

Of all the structural elements impacting nasal tip function and aesthetics, perhaps the single most important is *central tip support*. In the naturally stable and well-supported nose, central tip support is derived from a complex and interdependent architectural system consisting of both skeletal and soft tissue components. While the paired lower lateral cartilages provide the majority of direct tip support, the anterior nasal septum also provides considerable (secondary) tip support by undergirding, suspending, and buttressing the adjacent alar cartilage complex. Ligamentous interconnections, and the enveloping inner and outer nasal linings, also serve to greatly unify and consolidate nasal tip

support. However, in the overresected nose, central tip support is often severely compromised. Disrupted soft tissue support mechanisms, combined with overresection of the anterior nasal septum, typically lead to decreased tip projection and/or excessive tip rotation (4). Moreover, the loss of central septal support serves to accentuate the numerous other ill effects produced by overresection of the alar cartilages and/or nasal dorsum (1,4). Indeed, many of the unwanted stigmata of cosmetic rhinoplasty either are a direct consequence of or are markedly exacerbated by inadequate central tip support.

Not surprisingly, one of the most important objectives in restoration of the overresected nasal tip is reestablishing satisfactory central tip support. Arguably, the most effective method for achieving durable tip support is the *septal extension graft* (SEG)—a structural augmentation graft that is used to provide robust skeletal tip support (59–63). When available, septal cartilage is the preferred graft material since a thin, flat, and rigid piece of septal cartilage is ideally suited to the creation of an effective SEG. Septal cartilage is used preferentially over other graft materials since no other autologous tissue can approximate the unique combination of vigorous axial strength, transverse flexibility, unobtrusive thickness, and dependable shape retention.

In reality, the SEG is nothing more than an enlarged columellar strut graft that is sutured to the caudal septum for added support and stability (Fig. 184.10A–F). When minor deviations of the caudal septum are present, the extension graft can be sutured to one side of the caudal septum (opposite the side of deviation) to improve alignment and to create an overlapping joint of greater stability (64). Alternatively, when the caudal septum is midline, an end-to-end joint is necessary to prevent misalignment, and figure-of-eight sutures are used for graft fixation. However, the end-to-end configuration is inherently unstable, and extended spreader grafts or splinting grafts are sometimes needed to prevent deviation of the graft from midline, particularly in the presence of high closing tension.

Although the SEG is anatomically similar to a traditional columellar strut graft, structurally the SEG is considerably more powerful, and therefore far more versatile. Unlike a conventional columellar strut graft that has no direct contact with the nasal septum, the SEG is physically joined to the caudal septum, becoming a rigid extension of the bony

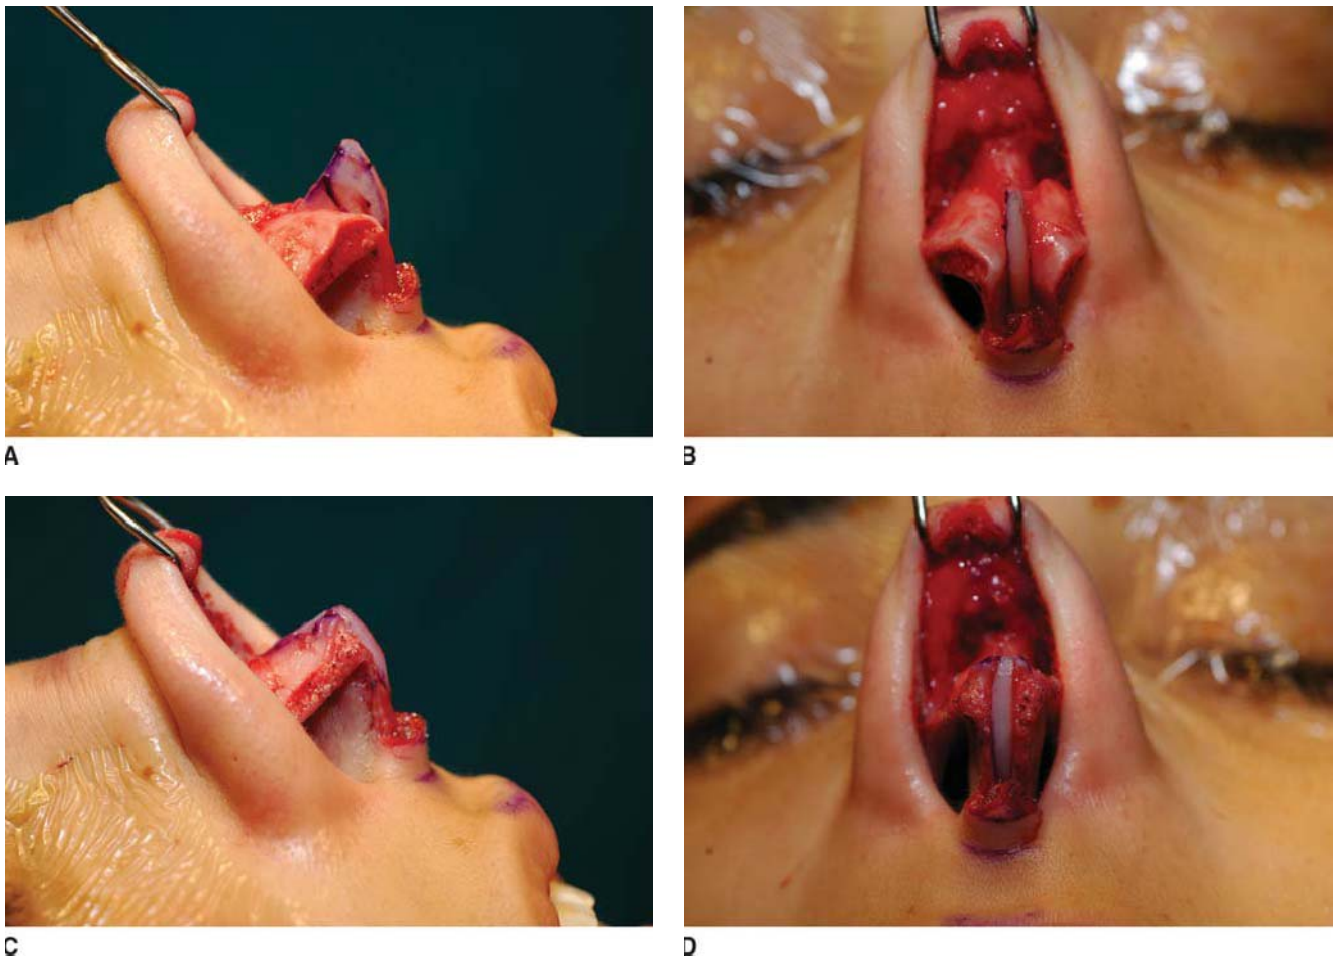

Figure 184.10 Example of SEG placement in primary rhinoplasty. **A,B:** Carved SEG placed end-to-end with the caudal septum. Note how the SEG extends beyond the weak, underprojected tip cartilages. **C,D:** Tip complex after alar cartilages are folded, advanced, and sutured to the distal SEG.

facial skeleton that can forcibly stretch nasal skin to increase nasal length and/or tip projection, and thereby dramatically alter tip location (Fig. 184.11A–D). Owing to the buttressing effect of the contiguous facial skeleton, the newly lengthened nasal septum can also resist progressive "shrink wrap" contracture of the internal or external nasal lining, making the SEG a reliable means of permanently stabilizing the re-expanded nasal base. Moreover, the newly created anterior septal angle also provides a secure skeletal fixation point for resuspension of collapsed and/or displaced alar cartilages (Fig. 184.12). By engineering graft dimensions to meet the individual cosmetic needs of the patient, the SEG can theoretically pinpoint tip position anywhere along the lower nose—limited only by the amount and quality of donor graft material and the constraints of soft tissue distensibility. And by custom contouring the caudal border of the SEG, profile deformities of the columella such as an overly flat or retracted columella can also be eliminated with SEG placement (64). Finally, the SEG also compensates for weakened intercrural ligamentous support commonly disrupted with the external rhinoplasty approach. Although a SEG fashioned from septal cartilage is preferred, double-layered conchal cartilage, or concentric-carved rib cartilage can be substituted when septal cartilage is unavailable.

Unlike the underprojected and foreshortened nose in which the SEG is the preferred option for increasing central

tip support, in the *overly long* nose, caudal septal lengthening is contraindicated. In fact, for patients presenting with the *caudal excess nasal deformity*, characterized by an overgrown (hanging) columella, an obtuse nasolabial angle, and a short upper lip, the overgrown septum itself can be used to provide direct central tip support (59,60,65). In this special circumstance, the medial crura are sutured directly to the caudal septum using a tongue-in-groove setback technique as described by Kridel et al. (66). In addition to improving central tip support and conserving graft

material, the tongue-in-groove method can also simultaneously correct the triad of characteristic deformities comprising the caudal excess nasal deformity (65). However, in cases of extreme caudal overgrowth, the caudal septum and/or the nasal spine may require trimming to achieve the cosmetically optimal profile configuration, and septal trimming must be preplanned in conjunction with septal graft harvest in order to avoid excessive narrowing of the caudal L-strut.

The paramount importance of central tip support is perhaps best demonstrated in Case Two. In this case, a healthy middle-aged female presented 30 years after primary rhinoplasty complaining of severe nasal airway obstruction. Examination revealed a pinched and underprojected nasal tip with thick, fibrotic nasal skin (see Case Two). Surgical findings revealed subtotal resection of both lateral crura and the complete absence of both upper lateral cartilages. Only the anterior nasal septum prevented complete structural collapse of the nasal tip. While mainstream rhinoplasty techniques favor structural replacement grafts to replace the missing upper and lower lateral cartilages, this profoundly overresected nose was successfully restored using only a SEG to augment central tip support. Although nonstructural contour grafts, including a shield graft and supratip onlay graft, were also used to enhance nasal contour, the placement of a SEG permitted a forcible reprojection of the neo-tip complex and a concomitant resuspension of both the previously unsupported vestibular skin and the inelastic outer soft tissue envelope. Consequently, despite a complete lack of skeletal sidewall support, both nasal valve patency and external nasal contour were successfully restored without structural sidewall grafts, underscoring the immense importance of central tip support to nasal form and function. The author attributes the favorable outcome to the biomechanical phenomenon of *sidewall tensioning*, an extremely useful technique made possible by rigid stability of the SEG. By first *forcibly reprojecting* the overresected nasal tip using the SEG, and then *stretching* the unfurled vestibular skin between the fixed piriform attachments laterally and the newly stabilized tip complex medially, both the inner and outer nasal linings were tightened or *tensioned*, much like a tent canvas is tightened by a large central tent pole. In addition to improved aesthetics resulting from increased nasal tip projection, improved sidewall tone and resiliency led to a demonstrable increase in (internal) nasal valve cross-sectional area and a corresponding increase in the threshold for inspiratory collapse.

Despite the theoretical benefits of sidewall tensioning, care must be taken to avoid excessive sidewall tension since excessive structural loads may exceed central tip support and lead to buckling or deviation of the septal/SEG complex. In extreme circumstances, such as a naturally weak

nasal septum or severely noncompliant nasal skin, extended spreader grafts are required to increase axial rigidity and prevent distortion caused by unavoidably high compressive loads (59,61–63,67). Whenever possible, tensioning forces should also be equally distributed between the right and left side to prevent unbalanced horizontal forces from displacing the SEG.

Lateral Tip Support

While sidewall tensioning alone may not always eliminate the need for additional structural grafting, as demonstrated above, a tensioned nasal sidewall greatly improves baseline soft tissue tone and rigidity relative to a lax or collapsed nasal sidewall, even when the lateral crural cartilage has been completely excised. Moreover, when a residual strip of crural cartilage is present, tensioning of the crural remnant further enhances structural support and may potentially obviate the need for structural grafting altogether (Fig. 184.11A–E) (see Case Three). Indeed, sidewall tensioning is a near universally applicable technique for treating and/or preventing lower nasal sidewall collapse that is equally effective in both revision and primary rhinoplasty.

However, among traditional treatment options for sidewall collapse, the *lateral crural strut graft* (LCS graft) has long been the therapeutic gold standard. Originally described by Gunter and Friedman (68), the LCS graft is a long strip of autologous cartilage sutured to the undersurface of the lateral crus (or the lateral crural remnant) for permanent splinting of the collapsed crural segment. Indications for the LCS graft include treatment of alar rim retraction, alar rim collapse, concavity of the lateral crus, and lateral crural recurvature—deformities that are commonly encountered in the overresected nose. Septal cartilage is typically the preferred graft material, but conchal or rib cartilage grafts are used in cases of septal cartilage depletion, while rib cartilage is preferred by some surgeons for its extra rigidity. In modest deformities, the LCS graft is approximately the same length as, or shorter than, the lateral crus. However, when used to correct severe alar collapse, alar retraction, or cephalic malposition of the lateral crus, the LCS graft must be elongated to extend beyond the lip of the piriform aperture for added skeletal support (68).

Although the LCS graft is generally effective at eliminating external contour deformities associated with sidewall collapse (33,59,68), the sheer bulk and weight of some LCS grafts may reduce internal nasal valve patency and/or lower the threshold for inspiratory collapse (1,33). Moreover, the mass effect associated with large structural grafts, particularly LCS grafts that extend beyond the piriform aperture, may result in effacement of the superior alar crease and/or unpleasant sensations with smiling or other facial movements (*Personal observation*).

Although structural grafting is unavoidable in some patients, limiting bulk within the lower nasal sidewall is of paramount importance, particularly in the naturally narrow nose where slit-like nasal valves are already predisposed to inspiratory collapse. Since the lateral crus has an average thickness of only 0.7 mm (39,40), some structural augmentation grafts, particularly those fashioned from conchal or rib cartilage, may add considerable thickness and bulk to the lower nasal sidewall. For example, the minimum natural thickness of conchal cartilage is approximately 1.9 mm (45), which is nearly three times the thickness of the lateral crus. Depending upon the positioning, rigidity, weight, and thickness of the graft material, structural augmentation grafts may improve alar contour, but they may also reduce the cross-sectional area of the nasal valve and/or lower the threshold for dynamic nasal valve collapse. Fortunately, the requirement for bulky structural augmentation grafts can be reduced or even eliminated by tensioning the nasal sidewall, a complementary technique that raises the threshold for internal nasal valve collapse without adding the weight, bulk, or mass of structural graft material. Indeed, stretching the lateral crural remnant between two fixed points not only increases baseline rigidity, it also serves to flatten, straighten, and stiffen a buckled or retracted crural remnant, thereby minimizing or eliminating crural concavity, recurvature, or cephalic retraction—structural benefits analogous to those achieved with the LCS graft (Figs. 184.11A–E and 184.12A–G).

While sidewall tensioning is worthwhile in virtually any case of lower sidewall laxity, the need for structural augmentation grafts cannot always be eliminated with tensioning alone, and an individualized and graduated approach to sidewall reconstruction is still required. In severe cases, the goal of avoiding excessive bulk or airway encroachment and simultaneously achieving adequate sidewall tone and contour is best achieved by aggressive tensioning of the nasal sidewall followed by the judicious and step-wise application of thin, yet rigid augmentation grafts—but only when tensioning fails to provide adequate structural support. Enhancing structural support while limiting graft volume not only optimizes airway patency, it also facilitates a more delicate and refined nasal tip contour, which better suits the aesthetic preferences of the typical revision rhinoplasty patient.

One the most common problems encountered in revision of the overresected nasal tip is cephalic retraction of the alar rim following an overzealous cephalic trim procedure. The severity of iatrogenic alar retraction varies widely, ranging from mild to severe, with the worst deformities arising in patients having both a congenitally high-riding alar rim and naturally weak alar cartilage, in which aggressive cephalic resection was followed by severe scar contracture (Fig. 184.2B). In the previously operated nose

with severely contractured and/or missing vestibular skin, satisfactory release and repositioning of the lateral crural remnant is rendered impossible, and auricular (chondrocutaneous) *composite grafts* are necessary to augment the deficient inner lining, and to physically buttress the alar margin against recurrent retraction (46,47). In contrast, the LCS graft remains the gold standard for correction of stubborn alar retraction in the absence of deficient nasal lining. However, a large percentage of revision rhinoplasty cases present with mild to moderate alar retraction and no significant lining deficiencies. Often these lesser deformities will respond favorably to a combination of sidewall tensioning and *alar rim grafts,* thereby obviating the need for traditional structural grafts.

The alar rim graft is a long, narrow cartilage graft that is placed (nonanatomically) in a precise pocket dissected along the alar rim (69,70) (Fig. 184.13A–E). Although diminutive in size, the alar rim graft provides increased

stability against lobular pinching and/or mild alar retraction (59,69,70). Alar rim grafts typically extend from the nasal dome medially to the mid ala laterally, and can be fashioned from septal, conchal, or costal cartilage donor material. Edges should be beveled to optimize graft camouflage and grafts wider than 3 to 4 mm are seldom necessary. Owing to the diminutive size and (nonanatomic) placement away from the internal nasal valve, airway impingement is avoided and external valve rigidity is greatly increased.

Treatment of mild alar retraction with alar rim grafts is enhanced by concomitant sidewall tensioning, which serves to tighten and straighten the lateral crural remnant and to oppose upward displacement of the alar rim. Suture fixation of the alar rim graft (medially) to the underlying tip complex is a helpful modification that stabilizes graft position to further buttress the nostril rim against cephalic displacement (Fig. 184.13B and C). In the previously operated nose, it is usually necessary to first unfurl the unsupported and contractured vestibular skin by disrupting all scar adhesions that prevent caudal repositioning of the crural remnant (Fig. 184.12A–D). If contracture release fails to permit appropriate repositioning of the crural remnant, structural augmentation grafts such as the LCS graft or the chondrocutaneous composite graft must be used to stabilize the repositioned crural remnant and to prevent recontracture.

Although alar rim grafts are often necessary in the previously operated nose, the small graft size reduces the demand for large amounts of donor cartilage. Consequently, a healthy and untouched quadrangular septum can usually provide enough graft material for fabrication of both a SEG and bilateral alar rim grafts. And by using nasal sidewall tensioning to initially stabilize and tighten the lateral crural remnants, coupled with alar rim grafts to reinforce the nostril rim against cephalic scar contracture, a large number of complex tip revisions can be effectively managed without any need for extranasal graft material. In addition to avoiding the time, expense, and potential side effects associated with the harvest and placement of extranasal structural grafts, septal donor cartilage offers the additional advantage of a structurally sound, yet characteristically delicate and slender tip contour, better suited to a narrow and refined nasal aesthetic (see Case Four).

Although sidewall tensioning is easiest when the (tensioned) crural length coincides exactly with optimal tip projection, sidewall tensioning can be accomplished in virtually any nose by first altering crural length to accommodate overprojected or underprojected alar cartilages. Alterations in crural length can be achieved through a host of conventional rhinoplasty techniques including the lateral crural steal technique for the underprojected tip (71), the lateral crural overlay or vertical lobule division technique for the overprojected tip (72,73), and the tongue-in-groove technique for both the over- and the underprojected tip (66). In conjunction with tensioning of the crural remnants, conventional suture techniques such as dome sutures, crural spanning sutures, or crural flattening sutures can also be used to further refine alar cartilage contour, while simultaneously preserving crural volume and further reducing dependence upon large structural grafts. Unlike the cephalic trim approach, these tissue-sparing techniques are not predicated upon further narrowing of the lateral crus, and the residual structural integrity of the alar cartilage is fully preserved. Finally, a variety of nonstructural cartilage grafts are also commonly needed to optimize nasal tip contour, symmetry, and alignment in the previously operated nose. A discussion of the myriad strategies used for tip grafting used in cosmetic rhinoplasty is far beyond the scope of this chapter, but primary rhinoplasty grafting techniques are equally effective in revision nasal surgery, and contouring grafts are routinely used to finesse the final cosmetic outcome.

REVISION OF THE SURGICALLY-DEVASTATED NASAL DORSUM

In a survey of 104 consecutive patients seeking revision rhinoplasty, Yu et al. (74) found cosmetic imperfections of the nasal dorsum to be the second-most common aesthetic concern prompting revision nasal surgery, surpassed only by nasal tip asymmetry. Perhaps the most devastating dorsal deformity prompting revision rhinoplasty is overresection of the nasal dorsum, a preventable technical error that may profoundly disrupt nasal bridge aesthetics. Depending upon both the extent and location of overresection, unsightly contour deformities may involve the bony upper vault, the cartilaginous middle vault, or the entire nasal bridge. Unlike the rigid bony dorsum that tends to resist deformation from soft tissue scarring, the comparatively soft and pliable cartilages of the middle vault are particularly susceptible to pinching and collapse from progressive scar contracture. Even when dorsal hump reduction avoids profile overresection, loss of (dorsal) septal width can lead to curvature or deviation of the dorsal septum, collapse or pinching of one or both upper lateral cartilages, or combinations therein. Proactive measures to augment and stabilize middle vault architecture are generally effective in avoiding such problems, but are often neglected at the time of primary rhinoplasty. Moreover, significant functional disturbances are also a common manifestation of nasal bridge deformities. Depending upon the extent of dorsal overresection and the length of the middle vault, symptoms may range from a mild cosmetic irregularity with minimal functional disturbance to a profound nasal deformity with near-total airway obstruction (Fig. 184.14).

Although the middle vault is considerably more susceptible to postsurgical scar contracture, overaggressive reduction of the bony nasal vault may also lead to conspicuous cosmetic deformities that are especially difficult to treat.

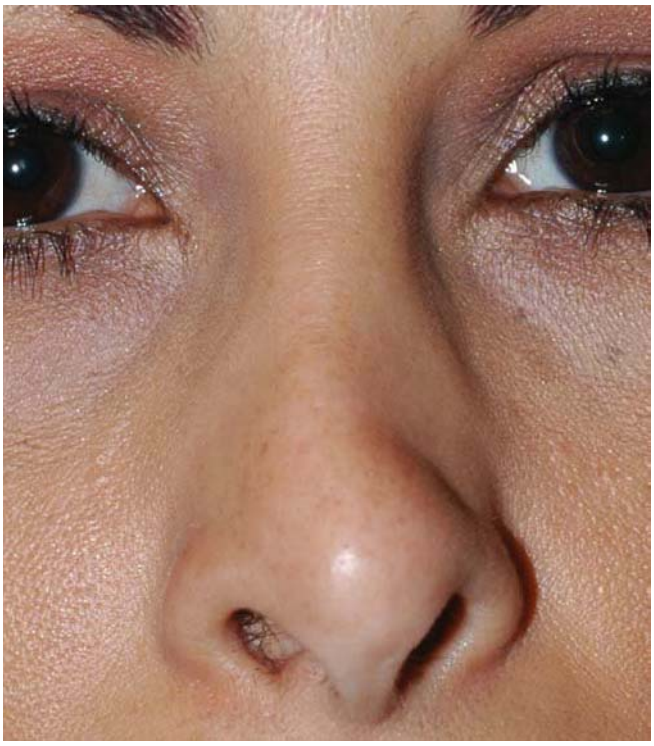

Figure 184.14 Postsurgical collapse of the nasal dorsum with severe functional impairment.

In addition to an underprojected and scooped bony profile, overaggressive reduction of the bony pyramid also leads to a widened and washed-out bony dorsum on frontal view. Variations of this characteristic appearance develop when faulty lateral osteotomies result in collapse, deviation, and/or comminution of one or both nasal bones. When combined with the wide natural variation in nasal bone morphology, a virtually limitless array of postsurgical bony vault deformities are possible, and the smooth, symmetric, and tapered configuration of a naturally elegant nasal bridge can be exceedingly difficult to recreate. Augmenting the overresected nasal dorsum such that the newly augmented segment seamlessly transitions with the underlying bony vault is indeed a formidable challenge, particularly when the underlying bony platform is also asymmetric and requires nasal bone repositioning. However, realignment of the asymmetric or deviated bony vault is a common aspect of revision rhinoplasty, and osteotomies are often essential for complete upper vault restoration. Alternatively, camouflage of bony irregularities with onlay grafts may also yield the appearance of a straight and attractive bony contour in some patients, and may be preferable to the unpredictability of widespread skeletal destabilization.

Osteotomies

Surgical modification of the bony pyramid is a challenging facet of *primary* rhinoplasty that often leads to patient dissatisfaction and revision nasal surgery. While some postsurgical bony deformities are easily corrected, severe bone deformities may prove extremely challenging, often in part due to instability from previous surgery. Even a seemingly simple task such as removing a residual bony hump or straightening a bony deviation may prove surprisingly difficult due to previous osteotomies and the potential for unpredictable bone behavior.

In general, the use of blunt-force osteotomies to modify bony architecture is more challenging in patients with a history of previous hump removal or previous nasal trauma since preexisting osteotomy or fracture lines can unexpectedly separate, collapse, or fragment with high-impact techniques. For that reason, low-impact alternatives are often less destabilizing and thus far more predictable. For resection of a residual bony hump or for smoothing of persistent dorsal surface irregularities, powered instrumentation such as a powered sagittal saw or powered reciprocating rasp (Stryker Instruments, Kalamazoo, MI) offers greater precision and less risk of excessive bone destabilization (75) (Fig. 184.15A and B). Powered instrumentation also facilitates sculpting of the bony vault that can eliminate minor bony asymmetries and potentially obviate the need for blunt-force osteotomies altogether (75). While powered instrumentation can improve accuracy and minimize bone destabilization, heat generated from powered instruments may increase bony callus formation. Callus formation is typically more common in adolescents and young adults, particularly males and athletic individuals. If left untreated, callus formation may sometimes progress to permanent osteogenesis and bony contour deformity. All patients at increased risk for callus formation should be advised about the possible need for long-term adjuvant treatment using low-dose triamcinolone injections. Although stubborn cases of callus formation may require prolonged serial injections, long-term results are usually satisfactory as long as treatment is not discontinued prematurely.

Although lateral osteotomies may behave unpredictably in the previously operated nose, revision lateral osteotomies are frequently unavoidable. Because nasal osteotomy sites or fracture lines heal slowly and initially by fibrous union, these areas of persistent bone weakness create a potential "path of least resistance" making it more difficult to control osteotome movement and to avoid opening previous osteotomy sites or fracture lines. Hence, caution should be exercised when performing revision osteotomies upon previously treated or previously fractured nasal bones. By the same token, individuals with brittle nasal bones—particularly the elderly—are also at increased risk for comminution from blunt-force osteotomies. In general, aggressive bone manipulation should be approached cautiously in the older patient since severe bone disruption may be compounded by lackluster healing responses and excessive narrowing or collapse of the bony vault. Because osteotome misdirection and excessive bone disruption are both accentuated by dull instrumentation, the use of a wet-stone–sharpened osteotome is recommended for all

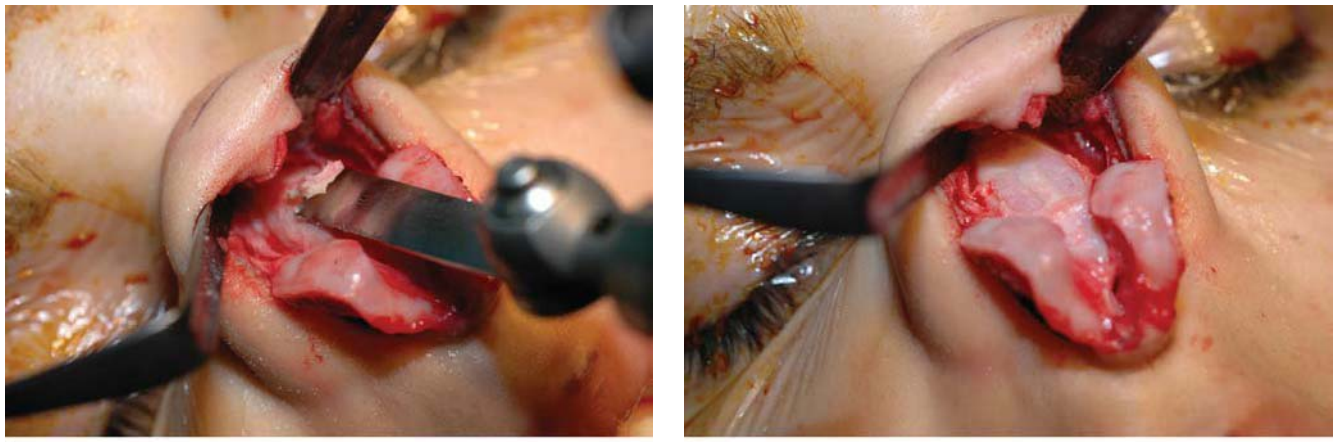

Figure 184.15 Removal of small bony hump using powered sagittal saw via the external rhinoplasty approach. **A:** Small bone shaving prior to complete hump removal. **B:** Smooth polished dorsum following hump removal with powered sagittal saw.

lateral osteotomies to improve osteotome control and minimize unwanted bone disruption. And while lateral osteotomies are sometimes indispensable, aggressive destabilization of the previously operated bony nasal pyramid is generally best avoided unless the potential benefits clearly outweigh the associated risks.

Perhaps the most common manifestation of the overresected nasal dorsum is the *inverted-V deformity*. The inverted-V deformity is produced by a conspicuous width discrepancy arising between the middle and upper nasal vaults following excessive hump removal. After excessive loss of dorsal height, the comparatively stable bony vault tends to remain wide, whereas the cartilaginous middle vault tends to collapse and pinch. The resulting step-off deformity produces a characteristic upside-down V-shaped shadow along the bony–cartilaginous junction from which the deformity derives its peculiar name (Figs. 184.3 and 184.14). Treatment of an inverted-V deformity arising from dorsal overresection inevitably involves augmentation grafting to restore lost dorsal height (see Cases three and five). However, while the inverted-V deformity is a near-universal sequela of excessive hump removal, inverted-V-type shadowing of the dorsum can also occur even after a conservative hump reduction where dorsal height remains appropriate. The formation of an inverted-V deformity despite adequate dorsal height is often due to failed lateral osteotomies and a persistent bony "open roof" deformity. In this circumstance, treatment involves either narrowing the overly wide bony vault to match the slender middle vault (i.e., close the "open roof" deformity) or augmenting the middle vault with spreader grafts to restore lost septal width. However, a combination of both methods is frequently most effective in achieving a uniform and attractive nasal dorsum while also optimizing the functional outcome. Patients at greatest risk for postsurgical deformities of the middle vault are those with short nasal bones and long slender noses, since the cartilaginous framework is disproportionately long, thin, and pliable. Prophylactic spreader grafts or equivalent measures such as upper lateral cartilage turn-in "spreader" flaps are recommended in high-risk patients at the time of primary rhinoplasty to reduce the likelihood of nasal bridge deformities and the subsequent need for revision surgery.

Dorsal Augmentation

Treatment of the overresected nasal dorsum is predicated upon restoring optimal dorsal height, as well as satisfactory contour, symmetry, and alignment. Successful dorsal restoration will produce a slender nasal bridge with smooth, parallel, and uninterrupted *brow-tip aesthetic lines* indicating a harmonious and attractive dorsal contour (59). In the absence of internal airway deformities, successful dorsal augmentation will also expand the nasal airway and produce a corresponding improvement in nasal airflow. In noses with overresection of the entire nasal dorsum, reconstruction is often achieved with simultaneous augmentation of the upper and middle vaults using a single augmentation graft spanning the entire nasal bridge. The choice between a conchal cartilage graft, a rib cartilage graft, a composite osseocartilaginous rib graft, or a semisolid (diced) cartilage graft varies according to the defect size, the need for structural rigidity, patient acceptance, and surgeon preference. In dorsal defects limited to 1 to 3 mm in depth, conchal cartilage can provide a satisfactory dorsal augmentation (see Case Three), but for larger dorsal defects, only rib cartilage can provide sufficient graft volume (see Case Five). When solid graft materials are chosen, proper three-dimensional graft contour is critical. In addition to a smooth and natural outer contour, the graft undersurface must be carefully sculpted to precisely complement the recipient dorsal topography.

Without a precise reciprocal interface to optimize surface contact and stability, the probability of graft displacement, mobility, and/or warping is greatly increased, particularly when using solid rib cartilage. Presoaking of the rib in saline, concentric carving of the rib cartilage, and avoidance of long thin cartilage constructs also help to prevent warping of the solid rib cartilage.

Perhaps the most reliable solid graft construct is the composite osseocartilaginous rib graft, which utilizes a large bone-on-bone interface to eliminate graft migration and warping (34,35). Osseocartilaginous grafts are harvested from the bony–cartilaginous fusion of the sixth to eleventh ribs, in order to restore the corresponding natural tissue constituents of the overresected nasal dorsum. To achieve an optimal reciprocal interface, powered instruments are used to create a flat recipient bed and to flatten the undersurface of the composite graft. Once the outer graft surface is sculpted to the desired three-dimensional contour, fixation is achieved using a percutaneous K-wire, which is removed in the office 1 week later. Owing to the large, raw bone-on-bone contact area and the secure initial immobilization provided by the K-wire, solid bone fusion is promptly established and long-term clinical outcomes are largely free of resorption, migration, or warping (34,35). Cosmetic results are favorable as long as the graft dovetails smoothly without overhangs, step-offs, or other contour imperfections. However, as with the traditional rib graft, excessive thinning of the cartilage component may lead to an increased incidence of postoperative warping.

An alternative method of dorsal augmentation is the diced cartilage–temporalis fascia (DC-F) graft (52,53). This semisolid construct is created by encasing 0.5- to 1.0-mm cubes of finely diced autologous cartilage in a sleeve of temporalis fascia to create a malleable yet durable dorsal augmentation graft (Fig. 184.16A and B). Depending upon the length and thickness of the skeletal defect, the DC-F graft can be used to augment either a portion of the nasal bridge or the entire nasal dorsum. Although the graft has limited structural rigidity, several key advantages make this an attractive alternative to the traditional solid graft construct. Perhaps the most important advantage is the malleable nature of the graft, which automatically conforms to contour irregularities of the underlying skeletal platform. Often minor irregularities of the skeletal platform can be

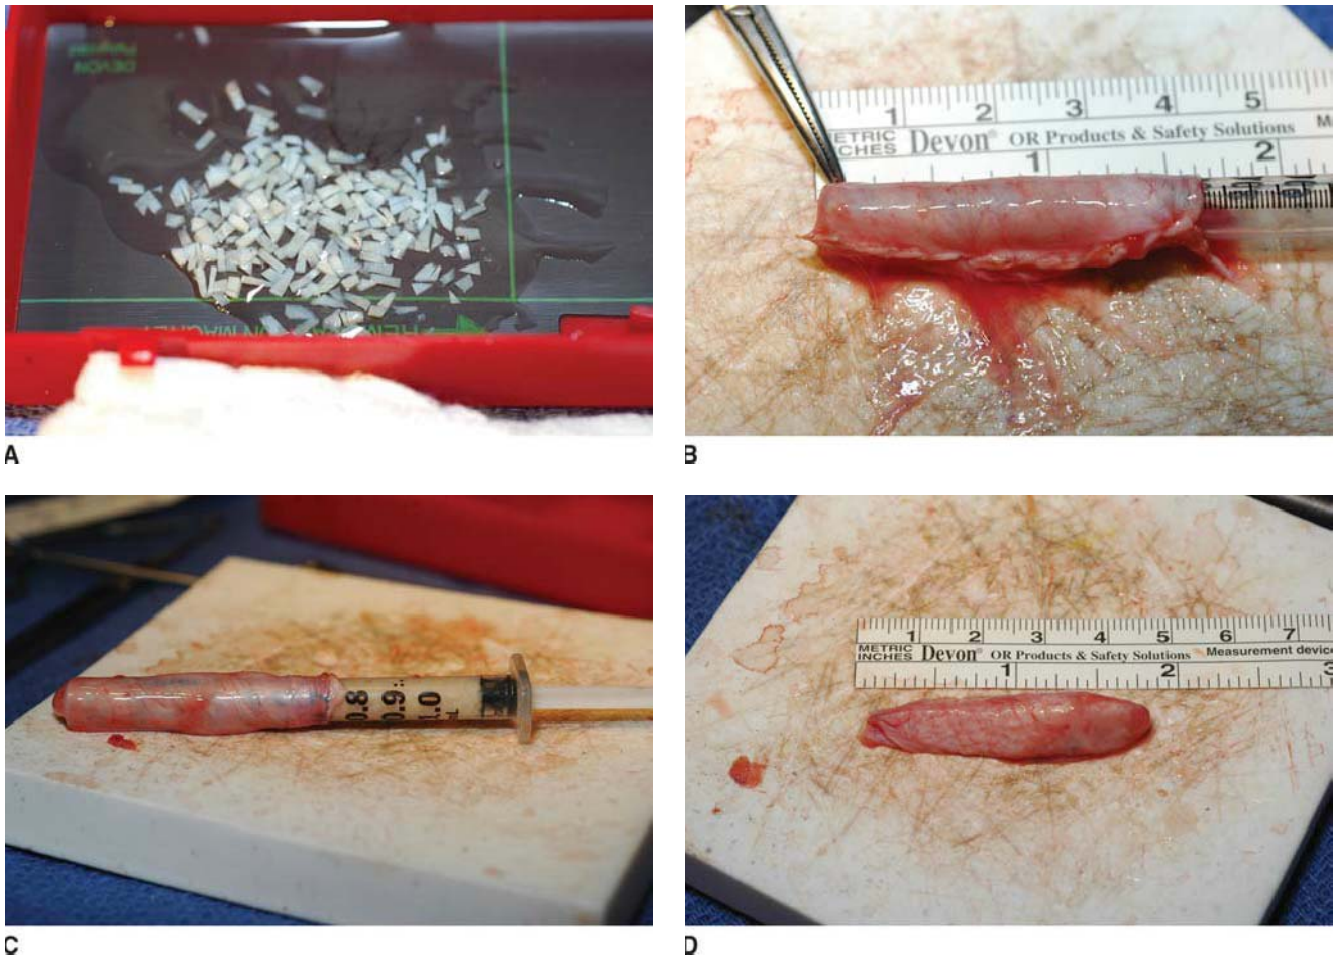

Figure 184.16 DC-F graft fabrication. **A:** Finely diced 1.0-mm cubes of autologous cartilage. **B:** Temporalis fascia sheath sewn around tuberculin syringe. **C:** Diced cartilage prior to injection into fascial sheath. **D:** DC-F graft prior to implantation.

camouflaged with the DC-F graft, creating the illusion of a straight and slender dorsum while avoiding unnecessary destabilization of the bony vault. Because the DC-F graft also provides a smooth and seamless interface with the surrounding nasal skeleton, grafts can be virtually any length or height without fear of migration, warping, or visible edge prominence. Even relatively small grafts used for radix augmentation blend seamlessly with the adjacent nasal dorsum without warping or step-off deformities. Despite rigorous sectioning of the donor cartilage, DC-F grafts have also shown excellent durability with no clinical or histologic evidence of resorption despite follow-up intervals of up to 7 years (52,53,76). In fact, owing to the clinical reliability of the DC-F graft, overcorrection is discouraged since volume loss is rare. However, long-term graft survival is contingent upon proper processing, since crushing, morselizing, or bruising of the cartilage is associated with partial necrosis and eventual loss of graft volume (77,78). Although the DC-F graft lacks structural rigidity that is typically required to lengthen a foreshortened nose, in patients with adequate skin elasticity, the DC-F graft may be combined with a SEG and extended spreader grafts to simultaneously increase dorsal height and nasal length. The growing incidence of large dorsal defects, combined with a corresponding increase in the number of graft-depleted patients, makes the DC-F graft an attractive and reliable treatment option for augmentation of the overresected nasal bridge.

Spreader Grafts

In patients with an attractive and symmetric bony vault and a satisfactory nasal profile; unsightly frontal deformities of the middle vault can still develop from isolated curvature and/or deviation of the dorsal septum. Inward collapse or pinching of one or both upper lateral cartilages can also create or aggravate middle vault deformities despite a satisfactory profile. Septal and upper lateral cartilage deformities are also a common element of more extensive dorsal deformities. Patients with long slender noses and/or short nasal bones are at greatest risk for postsurgical deformities of the middle vault following cartilage hump resection, since middle vault cartilages tend to be long, thin, and disproportionately weak.

In the absence of profile irregularities, treatment of middle vault deformities most often involves spreader graft placement. However, bilateral size-matched spreader grafts are not indicated in every patient, and a graduated and individualized approach to spreader graft placement is essential. Frequently, unilateral or partial-length spreader grafts achieve the best surgical results, and careful analysis is needed to properly individualize the treatment strategy. When using the external rhinoplasty approach, submucosal pockets are created along the dorsal septum for spreader graft insertion and suture fixation is performed at both ends of the graft for secure stabilization. The thickness, length, and number of spreader grafts typically vary according to individual anatomic needs, but the goal is always the same: mirror-image symmetry, sagittal alignment of the dorsum, and cosmetically appropriate width of the middle vault. For C-shaped curvatures of the dorsal septum, a single spreader graft, preferably with a reciprocal C-shaped curve, can be used to straighten and strengthen the dorsal septum while adding negligible width to the middle vault. In cases of middle vault pinching (with or without septal curvature), bilateral spreader grafts are often used to restore middle vault width and to augment septal support. Typically, partial-length spreader grafts are placed bilaterally, immediately below the bony–cartilaginous junction, to eliminate step-off deformities and prevent inverted-V-type shadowing. Depending upon the width requirements, grafts fashioned from septal cartilage can be used for mild to modest width deficiencies, whereas considerably thicker grafts can be fashioned from conchal or rib donor cartilage to accommodate larger defects. For cases of sagittal deviation or canting of the dorsal septum, conventional septoplasty techniques can sometimes restore sagittal alignment after release of the upper lateral cartilage remnants. In stubborn cases, spreader grafts are sometimes needed to realign and/or camouflage misalignment of the dorsal septum (79). However, misalignment of the cartilaginous septum is sometimes due to deviation of the vertical ethmoid plate, and blunt fracture of the vertical ethmoid bone is needed in this scenario to adequately mobilize and reposition the dorsal septum. When blunt repositioning of the vertical ethmoid bone fails to provide a stable septal realignment, a spreader graft can be extended cephalically and placed beneath the nasal bone (on the side of deviation) to permanently "shim" the central ethmoid complex and maintain midline positioning. When reconstructing the pinched middle vault, suture reattachment of the collapsed upper lateral cartilages is recommended to restore middle vault width and stability, and to prevent recurrent upper lateral cartilage collapse and pinching. In patients with distal canting of the dorsal septum, the use of clocking sutures can also be helpful to realign and further stabilize the dorsal septum (79).

Although spreader grafts are unquestionably the workhorse of middle vault reconstruction, graft survival is predicated upon a robust recipient blood supply, which is sometimes lacking in the middle vault—an area that is often predisposed to vascular insufficiency following minor tissue disruption. Despite secure fixation of the graft, minimal disruption of the septal mucoperichondrium, and gentle soft tissue dissection, spreader graft resorption may develop in susceptible individuals leading to persistent middle vault deformity. Patients with saddle nose deformities arising from trauma, autoimmune vasculitis, or chronic cocaine abuse are at particular risk for resorption of middle vault cartilage grafts, as are smokers, diabetics, and patients with other forms of microvascular disease.

The adage "as goes the septum, so goes the nose" attests to the difficulty of straightening a nose without first straightening the nasal septum. While traditional (endonasal) septoplasty techniques are often successful at straightening moderate deformities of the L-strut, conventional techniques may prove inadequate for the treatment of severe telescoping or accordion-type septal deformities. In these comparatively rare and challenging cases, extracorporeal septoplasty is often needed to achieve a satisfactory long-term realignment of the L-strut (80–83). Extracorporeal septoplasty involves elevating mucoperichondrium from both sides of the quadrangular septum and surgically removing the entire cartilaginous septum, leaving only a small remnant at the keystone area for later reattachment. Following cartilage explantation, the septal partition is subdivided along fracture lines and/or spurs to obtain flat segments that can be used to rebuild the outer septal partition. Cartilage fragments are then painstakingly reassembled and sutured in a mosaic-like configuration to produce a flat, uniplanar L-strut replacement graft. Permanent autologous scaffolding, such as septal cartilage or ethmoid bone, has been traditionally used to splint the fragile construct for added structural support, but the advent of resorbable polydioxanone (PDS) plate (Mentor Worldwide, LLC, Johnson & Johnson, Inc., New Brunswick, NJ) has become a popular and effective alternative for temporary (implantable) splinting of the reconstructed septal L-strut (80–82). Once assembled, the flat PDS-reinforced L-strut is reinserted into the mucosal pocket and sutured to the nasal spine and keystone area for improved septal contour, structural support, and airway patency. Although dramatic improvements in skeletal alignment are often the result of extracorporeal septoplasty, saddle-type deformities may occasionally result if the mucoperichondrium fails to adequately reperfuse the reimplanted cartilage. Although uncommon, saddling has been observed following the use of *unperforated* PDS plate for septal splinting, presumably since it more effectively blocks revascularization of the reimplanted septal cartilage (82). No cases of saddling were observed following unilateral application of the thinner, perforated version of the PDS plate, suggesting that this modification of PDS is more conducive to prompt cartilage revascularization. In either case, the use of bilateral PDS plate is discouraged since near-complete isolation of the reimplanted cartilage greatly increases the risk of ischemic resorption.

AFTERCARE

The conclusion of surgery marks the beginning of the recovery process. And while recovery is generally beneficial for nearly all patients, the speed, extent, and quality of the healing process varies widely among individuals and is often frustratingly slow. Monitoring the healing process and treating wound-healing derangements is a crucial aspect of revision rhinoplasty that may substantially improve the final outcome. Yet despite its importance, postoperative care is frequently neglected, opening the door for healing aberrations such as subcutaneous scarring, callus formation, or scar contracture, any of which may taint the final outcome. And while some patients require nothing more than periodic assessment to confirm appropriate healing, for others, regular intervention with appropriate adjuvant therapy is required to optimize the cosmetic and/or functional result. Indeed, for a small percentage of secondary rhinoplasty patients, a well-executed surgical procedure will fail to reach its full potential without appropriate and prolonged aftercare, and potential barriers to aftercare such as travel, work, school, etc. should be reconciled prior to surgery.

For many *revision* rhinoplasty patients, postsurgical monitoring and care is a long-term commitment that may last up to several years. However, it is in the first few hours after surgery that aftercare can have its biggest and most beneficial impact. From the moment the last suture is tied, aggressive efforts to mitigate soft tissue swelling and inflammation should commence, as it is far easier to avoid adverse tissue responses than to eliminate them.

One of the most effective ways to minimize soft tissue edema is with gentle wound compression. The application of a traditional cinch dressing, followed by uniform compression of the nasal dorsum with a padded aluminum splint, serves to gently compress the outer soft tissue envelope and minimize extracellular fluid accumulation. Splinting also serves to maintain nasal alignment and to protect the unstable nasal framework in the early days following surgery. In the same manner, internal nasal packing placed within the nasal cavity serves to support and tamponade the nasal tissues from within. By tightly packing the nasal vestibule with malleable packing material, the nasal tip is firmly compressed from both inside and out, and subcutaneous dead space in the lower nose is largely eliminated. Elimination of surgical dead space is particularly important in the thick-skinned nose since accumulation of blood beneath the skin flap often leads to subcutaneous fibrosis and unwanted skin thickening. It is also critically important to secure the compression dressing well in advance of extubation, since precipitous blood pressure elevations may occur during emergence from anesthesia. Under normal circumstances, the external nasal bandage is maintained for 1 week postoperatively, but the intranasal packing can be safely discontinued the following day as the threat of subcutaneous oozing has typically resolved. While the application of a compression dressing beyond 1 week may seem logical, extended application of the external bandage is generally counterproductive since progressive irritation and inflammation of the nasal skin usually offsets any potential benefits of prolonged nasal compression. For this same reason, the bandage is occasionally removed prematurely when contact dermatitis threatens to produce severe excoriation and blistering of the nasal skin.

Although considerable debate continues regarding the need for nasal packing, the cosmetic benefits derived from immediate tamponade of the nasal tip are generally well worth the transient discomfort associated with overnight packing.

In addition to an external nasal splint, bilateral septal splints fashioned from thin silicone sheets are also occasionally beneficial in supportive aftercare. Patients with nasal bridge instability resulting from extracorporeal septoplasty, aggressive osteotomies, severe skeletal trauma, or weak nasal cartilages often benefit from silicone splints placed high in the anterior nasal cavum to support the unstable middle vault framework. Low-profile septal splints, secured with a single anterior transfixion suture, can buttress the dorsum from below and greatly benefit the weak or unstable nasal framework until fibrous consolidation increases. Septal splints also help to maintain a straight nasal septum and to minimize septal swelling. Patients at increased risk for synechiae may also benefit from septal splints, which prevent raw mucosal surfaces from making contact. When placing septal splints, care must be taken to avoid septal necrosis from overtightening of the transfixion suture.

Another essential tool for reducing ecchymosis, edema, and inflammation is the immediate and continued application of ice. Although the nasal splint initially insulates most of the nose from the direct beneficial effects of ice, cooling of the adjacent soft tissues can greatly curtail swelling, bruising, and inflammation of the surrounding face, including the nose. In addition to continuous elevation of the head to 45 degrees (or higher) and placement of a damp cloth to prevent hypothermic skin injury, application of finely crushed ice over the nasofacial grooves, inner canthi, and glabella is maintained continuously for at least 24 hours after surgery, beginning in the operating room (Fig. 184.17). Aggressive application of ice is encouraged for all patients for the first 72 hours since inflammation and swelling are most likely to increase during the first 3 days following surgery. After 72 hours, prolonged intermittent application of ice is encouraged for all patients, but continued aggressive application of ice is strongly recommended for patients with thick nasal skin and those prone to excessive bruising or scarring. Although the application of ice is most beneficial in the first few days following surgery, ice can be useful to minimize transient nasal swelling for several weeks following revision rhinoplasty, and ice is particularly beneficial to control rebound edema following splint removal. While the application of ice often becomes tiresome, the frequent and prolonged application of ice can greatly improve the final cosmetic outcome, especially in patients prone to prolonged edema and subcutaneous scarring.

In addition to the proactive measures described above, patients should be advised to avoid all activities that exacerbate swelling or delay the resolution of edema. Prolonged recumbent posture, exercise, strenuous activity, valsalva, high salt intake, and nasal sunburn should all be carefully avoided until *acute* nasal swelling subsides—usually not less than 6 weeks for patients with thin or intermediate skin thickness and longer for patients with heavy skin. While these restrictions are often unpopular with patients eager to resume their previous lifestyle, supportive measures provide an important but transient opportunity to eliminate acute edema and avoid subcutaneous scarring. Hence, missing this brief window of opportunity in exchange for a few weeks of unrestricted activity is an unwise trade-off in the long run, and patients must be continually reminded about the necessity of these vitally important restrictions.

Figure 184.17 Continuous postoperative cooling using a surgical glove filled with crushed ice over a damp washcloth.

While medically supervised aftercare is a critical aspect of revision rhinoplasty, inevitably the postoperative healing process yields a few unwelcome surprises. Typically, this takes the form of transient nasal asymmetry and/or contour misalignment resulting from a swollen and increasingly taut soft tissue envelope. Since swelling is seldom symmetric, especially when the surgical procedure may have required asymmetric tissue disruption, temporary disturbances in alignment and symmetry are common in the weeks and months following a complex revision rhinoplasty. While often disconcerting to the patient, minor asymmetries resulting from soft tissue inflammation and edema usually resolve spontaneously, and patient reassurance is appropriate. Initiation of topical nasal steroid spray

(Fluticasone) as soon as the nasal lining is fully intact, typically 2 weeks following surgery, will also help to speed the resolution of edema and inflammation and safely eliminate minor asymmetries. Compressive taping of the nasal bridge can also be used in conjunction with nasal steroids to eliminate swelling of the dorsum or supratip soft tissues. Hypoallergenic paper tape is placed firmly across the swollen area and is worn overnight, and the tape is gently removed after soaking to minimize skin irritation or skin displacement.

As with soft tissue swelling, transient contracture of the skin envelope may also result in temporary distortion of the nose. Often this problem is most noticeable in the nasal base where linear contracture of the vestibular incision lines can lead to discrepancies in nostril shape or columellar contour. In addition to topical nasal steroids, insertion of soft nostril stents to dilate and stretch the skin incisions for several hours each day can lead to considerable improvement in nasal base contour and symmetry. Asymmetries of the dorsum and widening of the bony vault are also common problems after lateral osteotomies, particularly in younger patients who are highly susceptible to lateralization of the nasal bones from periosteal contracture. Often the nasal bones are properly aligned upon bandage removal, only to be displaced weeks later by periosteal scar contracture. To prevent permanent widening or asymmetry of the bony vault, nasal compression exercises are instituted until the bony vault narrows and stabilizes. Compression exercises involve the application of firm bilateral pressure directed toward the midline using the index fingertips placed just above the lateral osteotomy site. Firm pressure is maintained for 10-second intervals and is repeated five times each day as tolerated.

Low-Dose Steroid Injection

Since minor imperfections arise in nearly all patients and since these annoying problems generally resolve with time, conservative treatment, reassurance, and close monitoring are appropriate in the early weeks after surgery. However, despite prudent measures to contain surgical inflammation, a small number of patients—often those with thick, sebaceous nasal skin—will develop a vigorous and sustained inflammatory response. In the worst case scenario, uncontrolled inflammation may result in permanent cosmetic distortion and/or airway impairment from scarring or contracture. And while postoperative steroid injections may potentially diminish the inflammatory response, early intervention and sustained treatment is paramount even at the risk of localized steroid side effects. Fortunately, most patients do not develop a fulminant inflammatory response and can be managed effectively with topical nasal steroid spray (Fluticasone or equivalent) alone. However, even mild inflammation can lead to permanent soft tissue fibrosis if allowed to persist long enough, and additional treatment with injectable steroids is generally beneficial in any case of prolonged swelling.

In general, all patients with thick or intermediate skin thickness should be considered at risk for dead space fibrosis and permanent skin thickening, particularly following multiple prior surgeries. Although conservative treatment measures such as compression dressings, topical steroid sprays, taping, stenting, and massage are effective for the majority of primary rhinoplasty patients, the previously operated nose is far more susceptible to prolonged edema by virtue of cumulative circulatory impairment. Of all the adjunctive treatment measures available for controlling postsurgical swelling and edema, by far the most effective, yet also the most hazardous, is injection with *triamcinolone acetonide*, commonly known by its brand name Kenalog (Bristol-Myers Squibb Co., Princeton, NJ). When injected into the subcutaneous tissues, this long-acting synthetic glucocorticoid acts to reduce soft tissue edema and prevent dead space fibrosis. However, in susceptible patients this powerful anti-inflammatory agent may also result in dermal thinning, fat necrosis, cartilage graft resorption, localized infection, or telangiectasias. Unwanted side effects are more common when administered at full strength, or at frequent and prolonged intervals, but side effects can occur even at low doses in susceptible patients, particularly when administered soon after surgery. Fortunately, adverse reactions are uncommon at a starting dose of 5 to 10 mg/mL diluted in 1% lidocaine containing a 1:100,000 concentration of epinephrine, and small volumes of 0.05 to 0.1 mL are generally effective. In addition to minimizing injection site discomfort, the admixture of lidocaine with epinephrine also serves to minimize dispersal of triamcinolone from the targeted site. Because triamcinolone is typically slow-acting, assessment of the therapeutic response is delayed for a minimum of 4 weeks, at which time the initial dose can be repeated (if necessary) and/or carefully titrated to the desired effect. However, particular care should be exercised when treating callus formation in the thin-skinned rhinoplasty patient. Restricting the starting dose to 5 mg/mL and waiting 6 weeks before assessing the therapeutic response is recommended for thin-skinned patients who are at greater risk for the unwanted side effects of dermal thinning and telangiectasias. In general, triamcinolone treatment is also best avoided in the first 2 to 3 months following surgery to prevent erosion of autologous tissue grafts, unless severe fibrosis, contracture, and/or callus formation are threatening. In stubborn cases, repeated monthly injections are necessary before a sustained clinical improvement is achieved. Although low-dose triamcinolone injection is a useful adjunct in the actively healing nose, timely intervention is paramount since triamcinolone has little benefit in the fully healed nose.

Case Presentation One—"Completion Rhinoplasty"

Brief Case History

A healthy young female presents with a "bumpy," asymmetric, and oversized nose, 10 years after primary reduction rhinoplasty (see Fig. 184.19A–F). On frontal view, the bony vault is flat and asymmetric with lateral deviation of the left nasal bone. The middle vault is overly wide and both supra-alar creases are absent. The lobule is pinched, and the right ala is larger than the left. On profile, the tip is significantly overprojected and the nasolabial angle is overly obtuse. The dorsum is also overprojected, particularly in the middle vault. On oblique view, protrusions of the upper and middle vaults disrupt the dorsal line. On base view, the nose is markedly overprojected and the columellar pedestal is exceedingly wide. The caudal septum is partially obstructing the left nostril opening. The endonasal exam reveals deviation of the caudal septum into the left nasal vestibule, but the remaining septum is midline. No other endonasal pathology is observed. External revision rhinoplasty using septal and/or conchal cartilage grafts was recommended and performed.

Surgical Findings

Using the external rhinoplasty approach, the residual nasal framework was degloved. Healthy but malpositioned medial crura were encountered bilaterally, and the left alar cartilage was divided 2 mm below the dome. Both lateral crura were embedded in fibrous scar tissue and numerous blue monofilament sutures were removed from the tip and infratip. Large cephalic resections were noted bilaterally, with greater tissue excision from the right lateral crus. Crural width measured 6 mm on the right and 8 mm on the left, and both cartilages were buckled and malpositioned.

Surgical Steps (Fig. 184.18)

1. The nasal skeleton is degloved via the external approach.
2. The alar cartilage remnants are degloved and numerous blue monofilament sutures are removed from the tip and infratip.
3. The medial crura are degloved, and the distal 5 mm of cartilage (i.e., the footpods) are excised. Copious fibrous scar tissue is debulked from within the columella.
4. The membranous septum is divided, and the caudal septum and nasal spine are exposed.
5. The posterior septal angle and the nasal spine are trimmed approximately 3 mm.
6. Bilateral mucoperichondrial flaps are elevated over the caudal septum and lower ¾ of the quadrangular cartilage.
7. Septal graft material is harvested with L-strut preservation.
8. The medial crura are advanced inferiorly/posteriorly and sewn to the caudal septum ("tongue-in-groove" setback) to decrease tip projection and reduce nasolabial angle fullness.
9. The middle vault is degloved to reveal intact upper lateral cartilage/septal cartilage complex.
10. The upper lateral cartilages are sharply divided from the dorsal septum using a no. 15 blade, and after reflecting the overlying mucoperichondrium, a 4-mm pollybeak deformity is resected with straight Iris scissors.
11. A tapered (2 mm) resection of the bony hump is performed using a powered sagittal saw. Edges are rounded using a powered reciprocating rasp.
12. Bilateral (medial and lateral) osteotomies are performed to narrow the bony vault.
13. The upper lateral cartilages are sutured to the dorsal septum with running 5-0 vicryl.
14. A SEG is sewn to the right side of the caudal septum with 5-0 PDS to reproject and counterrotate the nasal tip position.

Figure 184.19 (*Continued*)

15. The medial crura are sutured to the caudal margin of SEG.
16. A shield graft is sutured to the infratip lobule with 5-0 PDS.
17. The domes are divided vertically, and both lateral crura are shortened by 8 mm at their cut edges. The lateral crural stumps are then folded upon themselves and sewn to the lateral shield graft with 5-0 PDS.
18. A paradomal cephalic excision is performed bilaterally to eliminate supratip fullness.
19. Lateral crural spanning sutures are placed bilaterally to flatten the lateral crural remnants.
20. A small batten graft is used to fill a concavity of the right crural cartilage.
21. Alar rim grafts are placed bilaterally (15 × 3 mm).
22. The subcutaneous pocket is irrigated with saline.
23. The skin is closed and an aluminum splint is placed.

Surgical Outcome

The postoperative nasal contour reveals a smaller, more symmetric, and more attractive nasal contour (see Fig. 184.19G–L). Despite deprojecting the nasal tip and markedly downsizing the skeletal framework, airway patency is preserved using sidewall tensioning to stretch and stiffen the overresected lateral crural cartilages.

Case Presentation Two—Restoration of Central Tip Support

Brief Case History

A healthy middle-aged female presented complaining of severe bilateral nasal airway obstruction and a pinched nasal tip. The past surgical history was remarkable for reduction rhinoplasty more than 30 years earlier. Physical examination revealed a pinched and underprojected nasal tip, and flaccid collapse of both nasal sidewalls (Fig. 184.20A–D). Palpation of the outer skin envelope revealed thick skin with moderate skin elasticity. Anterior rhinoscopy revealed a midline septum, inferior turbinate hypertrophy, swollen nasal mucosa, and bilateral nasal valve obstruction secondary to flaccid sidewall collapse. Palpation of the quadrangular septum revealed firm septal cartilage throughout. Surgical treatment with an external nasoseptal reconstruction using autologous septal cartilage and submucous resection of the inferior turbinates was recommended and performed.

Surgical Findings

Using the external rhinoplasty approach, the residual nasal framework was degloved. Healthy and intact medial crura were encountered bilaterally, but 95% of both lateral crural cartilages and 100% of both upper lateral cartilages were missing. The entire nasal septum including the dorsal septum, anterior septal angle, and quadrangular septum were fully intact.

Surgical Steps (Fig. 184.21)

1. The nasal skeleton is degloved via the external approach.
2. The membranous septum is sharply divided and bilateral mucoperichondrial flaps are elevated over the caudal septum and lower ¾ of the quadrangular cartilage.
3. Septal graft tissue is harvested with L-strut preservation.
4. An SEG (30 × 15 mm) is sutured to the caudal septum with three figure-of-8 sutures to project and counterrotate nasal tip position.
5. The medial crura are sutured to leading edge of SEG with 5-0 monocryl (percutaneous) transfixion sutures.
6. A shield graft is sutured to the infratip lobule with 5-0 PDS sutures.
7. The contractured vestibular skin is unfurled after lysis of adhesions.
8. The vestibular skin is stretched medially/anteriorly and sutured to the lateral shield graft.

G

H

Figure 184.20 (*Continued*) **E–H:** Corresponding postoperative views.

9. A tapered middle vault onlay graft is sutured to the underlying septum to correct the small saddle indentation created by projection of the collapsed nasal tip.
10. Nasal SMAS is excised from beneath the supratip skin for improved soft tissue distensibility.
11. A cartilaginous hump (1 mm) is shaved with a no. 15 blade.
12. A small bony hump is eliminated with the power rasp obviating the need for lateral osteotomies.
13. The subcutaneous pocket is irrigated with saline.
14. The skin is closed, and an aluminum splint is placed.

Surgical Outcome

The postoperative nasal contour reveals improved tip projection and elimination of lobular pinching (Fig. 184.20E–H). In addition to a favorable cosmetic result, internal nasal valve collapse and airway dysfunction were also eliminated without structural grafting of the nasal sidewalls.

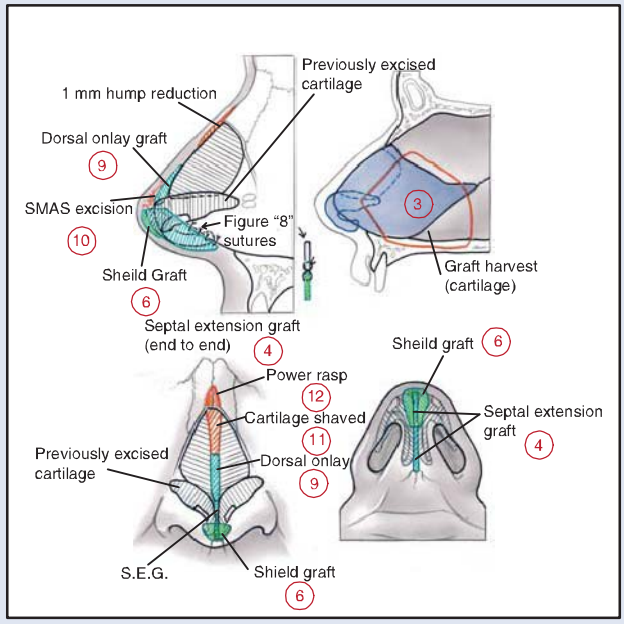

Figure 184.21 Rhinoplasty worksheet for case presentation two.

Case Presentation Three—Overresected Tip and Dorsum

Brief Case History

A healthy young female presents 1 year after primary rhinoplasty complaining of nasal airway obstruction, a "pinched" nasal tip, and an overresected nasal bridge (Fig. 184.22A–D). Examination revealed a conspicuous inverted-V deformity and marked underprojection of the rhinion, both consistent with overresection of a dorsal hump. The tip was markedly overrotated and pinched, and pinching was more severe on the right side. The columella was tilted to the right and a well-healed scar was visible at the mid columella. The nasal septum was midline and the quadrangular cartilage was fully intact to palpation. The inferior turbinates were hypertrophic.

An external nasoseptal reconstruction with septal and conchal cartilage grafts, and bilateral submucous turbinectomies was recommended and performed.

Surgical Findings

Using the external rhinoplasty approach, the residual nasal framework was surgically degloved. Overprojected, overrotated, and collapsed alar cartilages were encountered bilaterally. The right alar cartilage was previously divided vertically at the dome, and the intermediate crura were splayed by large amounts of fibrous scar tissue. The cephalic margin was also absent from both lateral crura and the crural remnants were retracted cephalically. Lysis of scar adhesions was necessary to free the crural remnants and permit caudal repositioning. Crural width measured 8 mm bilaterally, but both cartilages were buckled and malpositioned.

Surgical Steps (Fig. 184.23)

1. The nasal skeleton is degloved via the external approach.
2. The alar cartilage remnants are degloved, and fibrous scar tissue is excised from the infratip lobule.
3. Cephalic adhesions of the lateral crura are lysed to permit caudal repositioning of the crural remnants.
4. The membranous septum is divided, and the caudal septum and nasal spine are exposed.
5. Bilateral mucoperichondrial flaps are elevated over the caudal septum and lower ¾ of the quadrangular cartilage.
6. Septal graft material is harvested with L-strut preservation.
7. The middle vault is degloved to reveal overresection of the dorsal septum and upper lateral cartilages with pinching of the middle vault.
8. The nasal bones were degloved to reveal a short and overresected bony vault with bilateral open-roof deformities.
9. A fusiform-shaped conchal graft is fashioned from donor cartilage measuring 35 × 20 mm. The graft is bivalved longitudinally.
10. Submucosal pockets are developed on both sides of the dorsal septum, and the folded conchal "butterfly" graft is placed over the cartilaginous and bony septum at the rhinion and secured with 4-0 PDS mattress sutures.

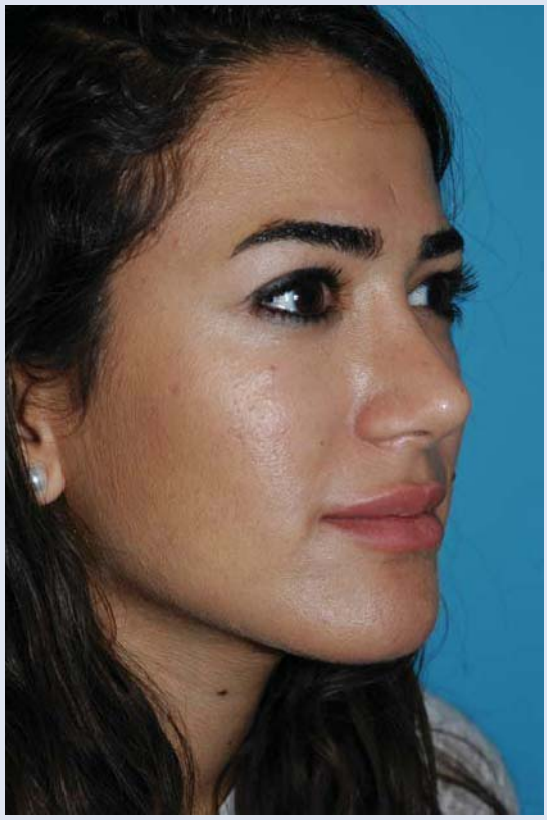
F



G

H

Figure 184.22 (*Continued*) **E–H:** Corresponding postoperative views.

11. Additional dorsal augmentation was achieved with a narrow septal cartilage onlay graft (with beveled edges) sutured atop the conchal butterfly graft.
12. Bilateral (medial and lateral) osteotomies are performed to narrow the bony vault.
13. The upper lateral cartilages are sutured to the outer butterfly graft with 5-0 Vicryl.
14. An SEG (septal cartilage) is sewn to the caudal septum in an end-to-end configuration using 4-0 PDS figure-of-8 sutures to lengthen the nose and counterrotate the nasal tip.
15. The medial crura are sutured to caudal margin of SEG with 5-0 Monocryl percutaneous transfixion sutures.
16. A double-layered shield graft is sutured to the infratip lobule with 5-0 PDS for additional tip counterrotation.
17. The domes are divided vertically, and both lateral crura are shortened by 5 mm at their cut edges. The lateral crural stumps are then folded upon themselves, advanced anteriorly, and sewn to the lateral shield graft with 5-0 PDS sutures to *tension* the collapsed and twisted lateral crural remnants.
18. A paradomal cephalic excision is performed bilaterally to eliminate supratip fullness produced by lateral crural advancement.
19. Alar rim grafts are placed bilaterally (15 × 3 mm).
20. The subcutaneous pocket is irrigated with saline.
21. The skin is closed, and an aluminum splint is placed.

Surgical Outcome

The postoperative contour reveals restoration of dorsal height with elimination of the inverted-V deformity and elimination of lobular pinching and tip overrotation (Fig. 184.22E–H). Nasal airway obstruction was also eliminated.

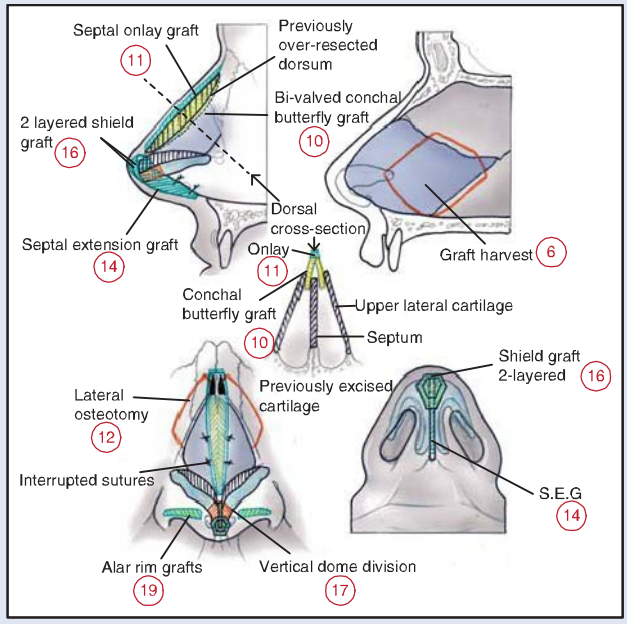


Figure 184.23 Rhinoplasty worksheet for case presentation three.

Case Presentation Four—Revision of the Narrow Nose

Brief Case History

A healthy young female presents 6 months after revision rhinoplasty complaining of nasal airway obstruction, a pinched nasal tip, and nasal asymmetry (Fig. 84.24A–D). The operative report from the primary rhinoplasty 1 year earlier described placement of bilateral lateral crural (onlay) "batten grafts" (harvested from the nasal septum) for treatment of lateral crural concavities. A second operative report from revision surgery performed 3 months later described removal of the batten grafts and placement of an interdomal suture. Frontal examination revealed a pinched lobule, flared and retracted nostrils, and a widened middle vault with effacement of the supra-alar creases. On profile examination, the columellar double-break was flattened and a persistent rhinion hump was noted. Anterior rhinoscopy revealed deviation of the caudal and quadrangular septum to the right side, constriction of both internal valves, and hypertrophy of the inferior turbinates. A membranous septum was palpable in the posterior–inferior aspect of the quadrangular cartilage. An external nasoseptal reconstruction with autologous septal cartilage and bilateral submucous inferior turbinectomies were recommended and performed.

Surgical Findings

Using the external rhinoplasty approach, the residual nasal framework was surgically degloved. The alar cartilage remnants were noted to be malpositioned, lacerated, and asymmetric (Fig. 184.25A and B). The left alar cartilage was divided vertically at the dome and again at the mid lateral crus, while the right alar cartilage remained in continuity with a vertical laceration of the right middle crus. The cephalic margin was missing from both lateral crura, and residual crural width measured approximately 8 mm, bilaterally. Despite the missing quadrangular cartilage from previous septal graft harvest, a 30 × 15 mm septal cartilage graft was removed from the upper quadrangular septum while preserving a 10- to 12-mm septal L-strut.

A B

Figure 184.25 Intraoperative photos for case presentation four. **A,B:** Exposure of misshapen and torn alar cartilages.

Surgical Steps (Fig. 184.26)

1. The nasal skeleton is degloved via the external approach.
2. The membranous septum is sharply divided and bilateral mucoperichondrial flaps are elevated over the caudal septum and lower ¾ of the quadrangular cartilage.
3. Septal graft tissue is harvested with L-strut preservation.
4. Septal flaps are reapproximated with 5-0 monocryl quilting sutures.
5. The nasal dorsum is degloved with blunt and sharp dissection.
6. The upper lateral cartilages are sharply divided from the intact dorsal septum, and a tapered 1.5 mm (submucosal) cartilaginous hump is resected.
7. A powered reciprocating rasp is used to remove the bony hump and create a straight dorsal profile.
8. A 25 × 4 mm (septal cartilage) spreader graft is inserted into a right submucosal pocket beside the dorsal septum and sutured at both ends with 4-0 PDS mattress sutures.
9. The upper lateral cartilages are sutured to the dorsal septum with 4-0 PDS mattress sutures.
10. Medial and lateral osteotomies are performed to narrow the bony vault and close the open roof.
11. An SEG (25 × 12 mm) is sutured to the caudal septum with three figure-of-8 sutures to project and counterrotate nasal tip position.
12. The medial crura are sutured to the leading edge of SEG with 5-0 monocryl (percutaneous) transfixion sutures.
13. A shield graft is sutured to the infratip lobule with 5-0 PDS sutures.
14. The domes are divided vertically, and both lateral crura are shortened by 5 mm at their cut edges. The lateral crural stumps are then folded upon themselves and sewn to the lateral shield graft with 5-0 PDS.
15. A cap graft is fashioned from septal cartilage and sewn atop the lateral crural stumps with 5-0 PDS.
16. Fibromuscular tissue removed from the tip and infratip is placed over the lateral crura for contour enhancement.
17. A right paradomal trim is performed.
18. An alar rim graft is fashioned from septal cartilage and secured in a left intracutaneous pocket.
19. The subcutaneous pocket is irrigated with saline.
20. The skin is closed, and an aluminum splint is placed.

Surgical Outcome

The postoperative nasal contour reveals a slender, feminine, and attractive nose (Fig. 184.24E–H) with normal airway function.

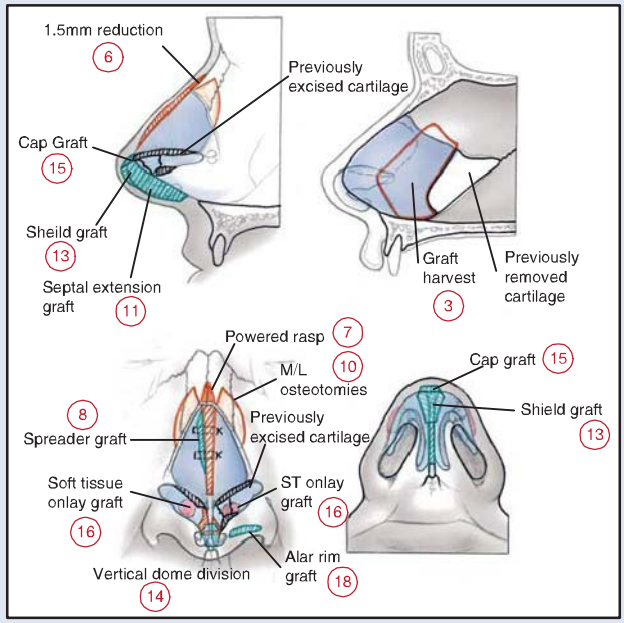

Figure 184.26 Rhinoplasty worksheet for case presentation four.

Case Presentation Five—Revision of the Severely Collapsed Nose

Brief Case History

A healthy young female presents 18 months after severe nasal trauma complaining of severe nasal obstruction and a wide, flat, and crooked nasal vault. Four weeks prior to injury, the patient underwent reduction rhinoplasty for treatment of a wide nose with severe airway obstruction. Preoperative photos reveal a naturally wide nose with adequate tip projection and a pseudo-hump from a deep radix (see Fig. 184.28A–D). Severe deviation of the caudal septum is seen on basal view. Postoperative photos reveal overresection of the rhinion, deprojection of the nasal tip, and significant additional widening of the tip and dorsum (see Fig. 184.28E–G). Upon presentation 18 months after injury, frontal examination revealed a splayed and scoliotic nose with impaction of the bony vault, pronounced rightward deviation of the dorsal septum, and a wide, amorphous nasal tip (see Fig. 184.28H–K). On profile examination, conspicuous loss of dorsal, tip, and columellar projection were evident, while the basal view revealed a severely underprojected nose with widening and impaction of the caudal septum.

Surgical Findings (see Fig. 184.29)

Using the external rhinoplasty approach, the residual nasal framework was surgically degloved. Small medial crural remnants were present in the columella, but approximately 90% of the lateral crura were missing and the remnants were noted to be embedded in scar tissue and malpositioned (see Fig. 184.29A–C). Numerous scar adhesions were lysed to unfurl the contractured vestibular skin. Upon degloving of the middle vault, the dorsal septum was found avulsed from the nasal bones, partially collapsed into the nasal cavity, and canted approximately 30 degrees to the right of midline. The caudal septum was deviated approximately 90 degrees from sagittal and was protruding into the right nasal passage. Accordion-type collapse of the left upper lateral cartilage was also observed, but the bony dorsum revealed no significant evidence of surgical or traumatic alteration.

Surgical Steps (Fig. 184.27)

1. The nasal skeleton is degloved via the external approach.
2. The alar cartilage remnants are degloved, and the contractured vestibular skin is unfurled with lysis of scar adhesions.
3. The entire cartilaginous septum, including the L-strut, is removed for donor graft material.
4. A 5-cm segment of full-thickness cartilage was harvested from the right fifth rib via an inframammary fold incision.
5. Concentric rib carving is used to create a 3.5 × 1.2 cm columellar strut graft.
6. The strut graft is notched at its base and sutured to the nasal spine with 4-0 PDS figure-of-8 suture passed through a transverse drill hole.
7. A 2.0 × 0.7 cm (dorsal) septal replacement graft was also fabricated from concentric carved rib cartilage.
8. The septal replacement graft was sutured to the upper lateral cartilages at the K-area and to the columellar strut to reconstitute the L-strut.
9. A 4 × 5 cm piece of deep temporalis fascia is harvested from the right temporal scalp.
10. Initially using a 3.0 syringe, and then a 1.0 mL syringe as templates, the temporalis fascia is sewn into a tapered cylinder measuring 4.0 cm in length. The proximal end is sewn shut.

11. The remaining rib and septal cartilage is diced into 1.0 mm^3 cubes and used to fill the fascial cylinder with diced cartilage.
12. The DC-F onlay graft is inserted into a precise subcutaneous pocket overlying the nasal dorsum and lower glabella and positioned using percutaneous guiding sutures.
13. The medial crural remnants and vestibular skin are advanced anteriorly and sewn to the columella strut graft with a 5-0 PDS suture.
14. The subcutaneous pocket is irrigated with saline.
15. The nasal skin is closed under moderate tension and measured tip projection increased by 12 mm.
16. A gentle compression dressing and aluminum splint are placed.

Surgical Outcome

The postoperative contour reveals the restoration of dorsal and tip projection with a corresponding reduction in nasal width (Fig. 184.28I–M). Smooth and attractive dorsal lines are achieved with diced cartilage wrapped in temporalis fascia, while tip contour was restored using concentric-carved solid rib cartilage. Nasal airway dysfunction was also eliminated.

SUMMARY

Revision rhinoplasty ranks among the most technically demanding of all elective cosmetic surgical procedures. In addition to the technical challenges associated with profound cosmetic derangements, surgically compromised tissues and the emotional impact of an unexpected nasal deformity add to the already formidable treatment challenge. Effective treatment planning mandates a thorough assessment of the nasal tissues (both internal and external), the status of the nasal airway, and the cosmetic nasal deformity, as well as an equally careful assessment of the patient's emotional well-being and their cosmetic treatment objectives. A host of contemporary reconstructive techniques are now available for effective restoration of the complex postsurgical nasal deformity, and the efficient, skillful, and artistic application of cartilage graft material is the cornerstone of surgical restoration. Familiarity with each graft type and its unique biophysical properties is crucial to successful graft application, and an artistic sensibility to guide surgical intervention is invaluable. For most patients, the goal of an attractive, durable, and fully functional nose can be achieved when these techniques are executed successfully, and the emotional impact of a successful revision rhinoplasty can be both dramatic and immensely gratifying for patient and surgeon alike.

HIGHLIGHTS

- An in-depth review of *skeletal overresection*–perhaps the most common problem prompting complex revision rhinoplasty—including the cosmetic, functional, and anatomic sequelae of the overresected nose.
- A discussion of the unique psycho-social challenges of revision rhinoplasty, as well as several commonly encountered psychological disorders that may adversely impact patient care.
- Fundamental aspects of preoperative patient evaluation with emphasis upon tissue tolerance and the key prognostic indicators for surgical success.
- Advantages and disadvantages of various anesthetic options, surgical approaches, and potential graft materials, as well as optimal timing for favorable treatment outcomes.
- Dismantling or "deconstructing" the previously operated nose with respect to minimizing structural destabilization, vascular compromise, and soft tissue scarring.
- The strategic use of autologous graft materials for the permanent restoration of function and beauty to the upper, middle, and lower thirds of the nose.
- The importance of (postoperative) supportive care for preventing and managing adverse wound-healing responses.

The Aging Forehead

185

Kian Karimi *Peter A. Adamson*

Addressing the upper third of the face is an important component of facial rejuvenation. For many patients, descent of the eyebrows leads to exacerbation of periocular aging, which is inadequately treated with blepharoplasty. Without correction of eyebrow ptosis, the aging face often conveys fatigue and even anger. Forehead rejuvenation procedures have been utilized with increasing frequency over the last several decades. The forehead lift, or the "face-lift of the upper third," is an essential tool in providing a harmonious rejuvenation in patients.

HISTORY

As examined in a recent review by Matros et al. (1), changes in eyebrow position and shape with aging have been described and refined for the past four decades. Some of the earliest descriptions of brow lifting date back to 1919 as described by Passot, Hunt, and Lexer (2). Vinas is credited for noting the difference between static and dynamic rhytids and importantly recognized that treatment would differ between the two types, including the necessity to free adhesions over the orbital rims to mobilize and elevate the brows. An important development in brow lifting occurred in 1992 with the first description of the endoscopic technique (3). Despite multiple modifications of the brow lift trending toward less invasive approaches purporting lower complication rates and higher patient acceptability, a recent review by Cilento and Johnson of over 1,000 coronal or trichophytic brow lifts demonstrated extremely high rates of patient satisfaction with an acceptably low complication rate including no permanent motor nerve dysfunction.

FOREHEAD ANATOMY

The forehead represents the upper third of the face and can be divided into vertical fifths as well, yielding five aesthetic subunits: the central forehead, lateral temporal units, and the brows. The lower anatomic boundaries include the supraorbital rim, nasal root, and bony zygomatic arches. The supraorbital rim is usually the landmark by which brow ptosis is measured. The trichion and natural hairlines represent the upper limit. Perhaps the most important division of forehead anatomy lies on either side of the temporal line, which divides the temporal regions from the forehead and intersects with the peak of the brow in both men and women.

Branches of the external and internal carotid arteries provide the blood supply to the forehead. The external carotid artery provides the superficial temporal artery and subsequent zygomaticotemporal branch, which supply the temple region and lateral forehead. The internal carotid artery supplies the midforehead via branches of the ophthalmic artery, the supratrochlear artery medially, and the supraorbital artery laterally, typically 2.5 cm lateral to the midline (Fig. 185.1).

Sensation is provided by the supraorbital and supratrochlear nerves, which are branches of the trigeminal nerve (V). The supratrochlear nerve exits the orbit, alongside the artery, and travels through the medial corrugator supercilii, providing sensation to the medial forehead. The supraorbital nerve exits the superior orbit through a foramen along the rim in nearly 90% of patients but can also exit the orbit through a foramen up to 1.5 cm above the orbital rim (4). Laterally, sensation is provided by the lacrimal (V1), zygomaticofacial (V2), and auriculotemporal (V3) nerves. Motor innervation is provided exclusively by the notoriously fragile temporal branch of the facial nerve.

The temporal branch exits the parotid gland and courses superiorly from a point 1.5 cm below the external auditory canal, crosses the zygomatic arch approximately 2.5 cm (0.8- to 3.5-cm range) anterior to the auditory canal, and runs superomedially toward the frontalis muscle but remains 2 cm posterior to the lateral bony orbital rim. This nerve can be reliably predicted by its relation to what

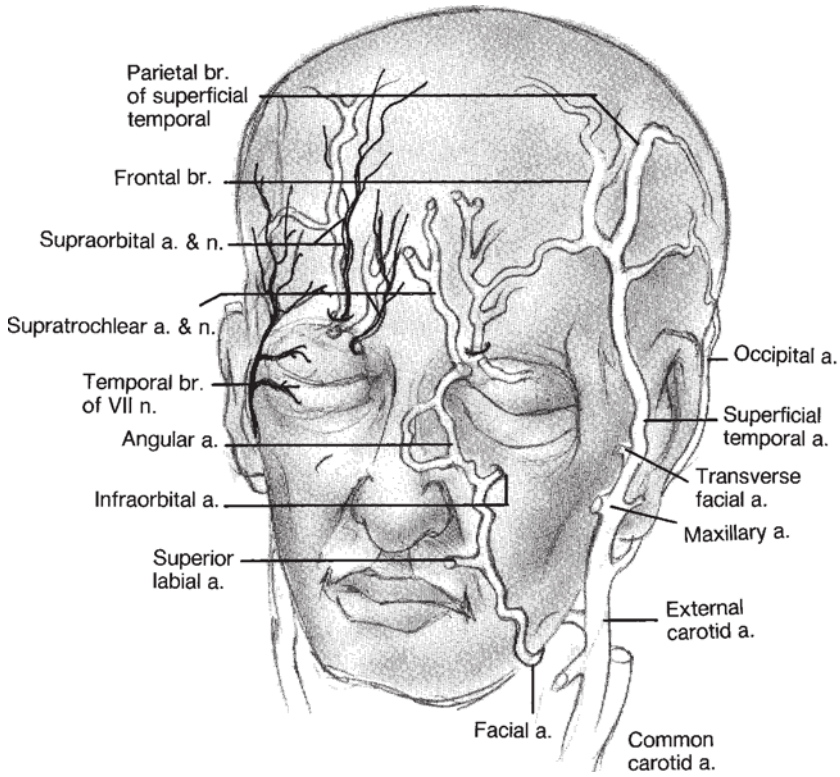

Figure 185.1 Vessels and nerves of the forehead. The major arterial and sensory innervation is through the supraorbital vessels and nerves. They arise about 2.5 cm from the midline. The temporal branch of the facial nerve is the most functionally significant.

is known as the cephalic or "sentinel vein," running just superficial to this vessel. The temporal branch remains just deep to the temporoparietal fascia and runs within the substance of this fascia, which is continuous with the superficial musculo-aponeurotic system (SMAS) inferiorly.

The forehead is an extension of the scalp and thus consists of the same layers, which, from superficial to deep, are the skin, subcutaneous tissues, galea and frontalis muscles, loose supraperiosteal areolar tissue, and pericranium (Fig. 185.2). The galea separates along the superior origin of the frontalis muscle, which divides the galea into superficial and deep layers. The posterior galea is in the same plane as the superior orbital septum. Lateral eyebrow ptosis has been described to be further exacerbated by a ptotic "galeal fat pad," which is usually fully enveloped by the deep galeal fascia but may be dehiscent in some individuals, accelerating lateral brow ptosis (4). Laterally, the galeal layer is contiguous with the superficial temporal parietal fascia, both of which fuse at the zygomatic arch. The loose subgaleal and subtemporal parietal fascial layers allow for free mobility of the galea, facilitating facial expression.

The frontalis muscle is the primary elevator of the brow and is the most significant contributor to horizontal forehead rhytids. Inferiorly, the frontalis interdigitates with the orbicularis oculi muscle, the skin of the eyebrows, and the root of the nose (Fig. 185.3). The frontalis muscle also blends with the corrugator supercilii and procerus muscles medially. The corrugator supercilius muscle, also known as the "muscle of grief," is the only muscle of facial expression to arise from bone. After originating from the medial aspect of the supraorbital arch, it passes obliquely, deep to the frontalis and orbicularis muscles, to insert by interdigitation with these muscles throughout the medial half of the eyebrow, causing characteristic vertical and oblique rhytids. The unpaired procerus muscle is pyramid shaped and arises from the fascia over the nasal bone and upper

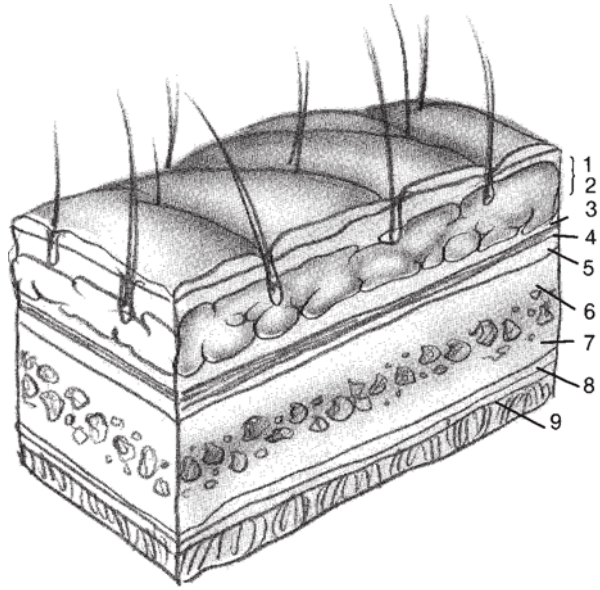

Figure 185.2 Forehead skin. "SCALP" refers to the layers of the forehead skin. *1*, Skin; *2*, subcutaneous tissue; *3*, epicranial aponeurosis (galea and frontalis m.); *4*, lax areolar tissue; *5*, pericranium; *6*, outer table; *7*, inner table; *8*, dura mater; *9*, arachnoid.

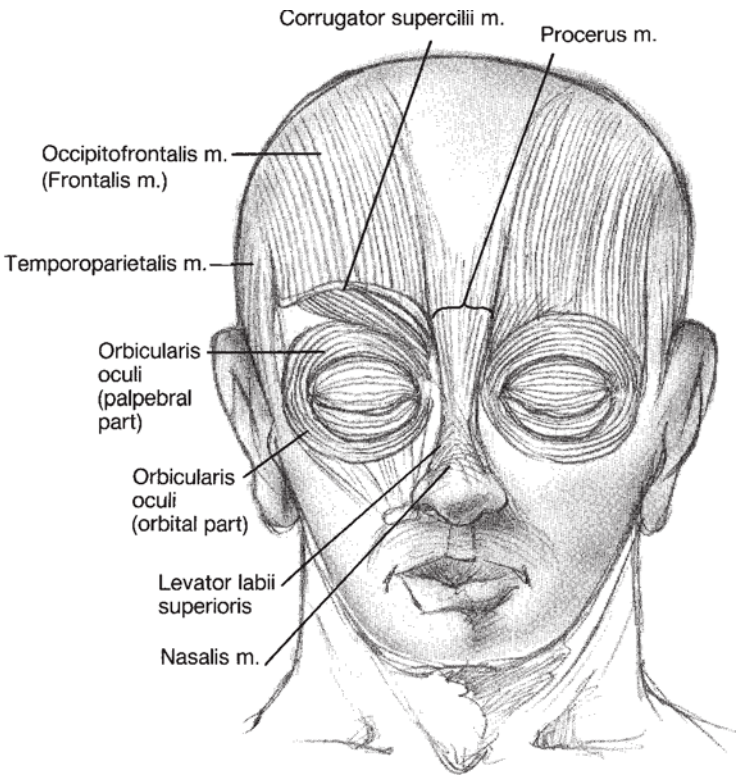

Figure 185.3 Forehead muscles. Forehead muscle activity causes the development of the rhytids associated with aging. The frontalis muscle produces horizontal forehead rhytids, the corrugator supercilius muscle vertical glabellar rhytids, and the procerus muscle horizontal glabellar rhytids.

lateral cartilages of the nose and inserts in the skin between the eyebrows, producing horizontal glabellar rhytids. The orbicularis oculi muscle also serves as a brow depressor. The depressor supercilii muscles are a minor contributor to brow depression.

In a discussion of anatomic structures that contribute to the upper face aging process, it has been recognized that superficial temporal fascia "instability" plays a role in lateral brow ptosis due to its weak adhesion between the superficial and deep temporal fascial planes, with the sole support of the superficial fascial plane being its attachment to the frontal bone along the rim of the temporal fossa in the "zone of adhesion" and a loose attachment to the superior–lateral orbital rim called the "orbital ligament," thought to represent a condensation of the superficial temporal fascia (4). It is also postulated that paucity of frontalis insertion laterally, and the stabilizing forces provided by the supraorbital and supratrochlear neurovascular bundles, explain why lateral eyebrow ptosis occurs to a far greater degree than medial or midbrow ptosis.

PHYSIOLOGY OF AGING

In youth, the forehead, temple, and glabella are unfurrowed. The hairline is irregularly irregular, and there is no evidence of male-pattern baldness or thinning hair in women. The transition between the thicker infrabrow skin and upper eyelid skin is of particular importance. In youth, the higher brow position allows for a well-demarcated contour of the lateral supraorbital rim above and an obvious upper eyelid fold.

With aging, the upper third of the face undertakes multiple changes (Fig. 185.4). The corrugator supercilius muscle may be the initiating factor to the aging process of the upper face by producing vertical and oblique glabellar skin lines through its transverse and oblique fibers, respectively (4). It is the interdigitation of the corrugator with the orbicularis, procerus, and depressor supercilii muscles that further causes medial eyebrow depression and glabellar rhytids. As the skin weakens over time and becomes less elastic, these rhytids become permanent. Additionally, loss of subcutaneous tissue and increased skull bone resorption is noted. Descent of the lateral third of the brow (lateral to the deep temporal fusion line) is discussed previously in this chapter. A visual field defect can result in advanced cases of lateral eyebrow ptosis, especially when compounded with upper eyelid ptosis. This "closed eye" appearance is associated with sadness, fatigue, anger, and aging.

With descent of the brows, there is a tendency of the frontalis muscle to increase activity dynamically to counteract the irritant effect of the redundant tissues on the eyelids, thereby initially creating superficial and transient rhytids that become deeper and permanent over time.

Each individual has unique facial expressions and, thus, each develops a unique pattern of upper facial rhytids and eyebrow position. The patient's skin type, photodamage, tobacco abuse, and many other factors also affect the facial parameters associated with aging.

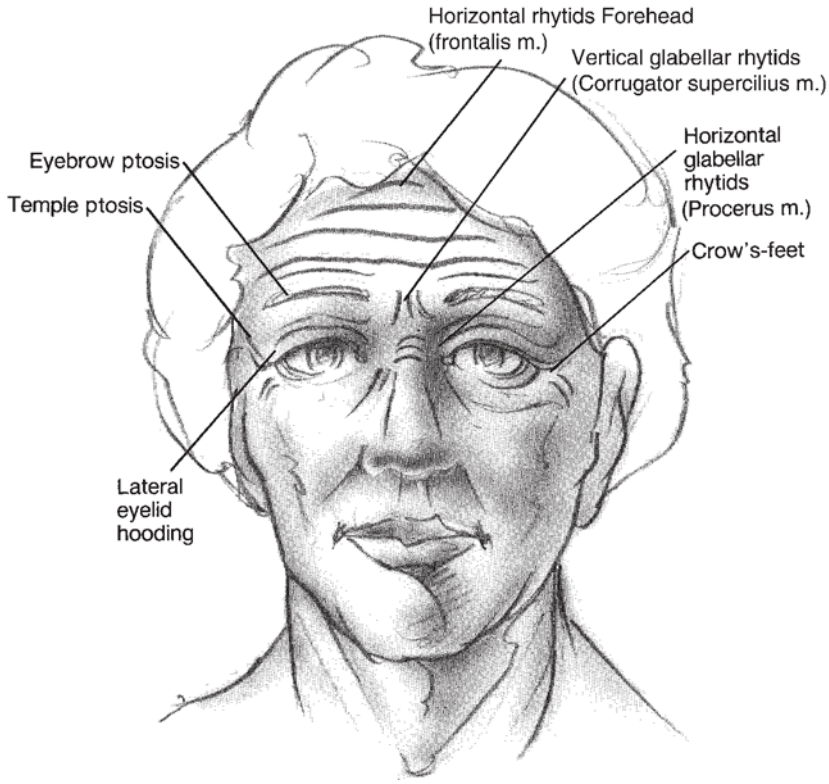

Figure 185.4 Physiology of aging. Ptosis initially occurs at the lateral brow but eventually involves the entire brow and forehead. Rhytids are caused by voluntary and involuntary muscle activity.

BROW AESTHETICS

The youthful brow, as classically described by Westmore in the 1970's, is an arch whose apex terminates above the lateral limbus of the iris, with the medial and lateral ends of the brow at the same horizontal level. With evolving concepts of beauty, the ideal brow apex has been described anywhere from the lateral limbus to the lateral canthus (5–7). A recent study found that the deep temporal fusion line is the most precise indicator of brow peak position, which makes the most sense intuitively and anatomically. The club-head–shaped medial brow should be in line with a vertical line drawn through the insertion of the ala of the nose. It arches superolaterally above the supraorbital rim to its apex somewhere between the lateral limbus and lateral canthus and tapers into a handle shape to end laterally at an oblique line drawn through the ala of the nose and the lateral canthus. The medial and lateral ends of the eyebrows should lie in the same horizontal plane. In men, the brow is ideally at the level of the supraorbital rim whereas in women the brow should peak above the supraorbital rim. The more lateral the apex of the brow, the more feminized the brow is. Eyebrow hairs are typically thicker in men and may extend in any direction. A lower, thicker brow may still be considered attractive in women, depending on its harmony with their overall facial aesthetics.

ASSESSMENT

Each patient must specify his or her particular concerns if the appropriate procedure is to be chosen for forehead rejuvenation. Oftentimes, a patient will seek correction of lateral eyelid hooding and request blepharoplasty when the ideal procedure may well be one to elevate ptotic brows. During analysis for the patient seeking facial rejuvenation, the surgeon must demonstrate the patient's own natural brow position in repose as most people with brow ptosis will unconsciously elevate their brows. A previous history of upper blepharoplasty or brow lifting procedures may produce a relative lack of upper eyelid skin for lifting procedures. Additionally, a history of laser-assisted in-situ keratomileusis surgery or dry-eye problems must be considered prior to brow lifting since a transient lagophthalmos following surgery is not uncommon. Patients with alopecia may be at an increased risk for surgical hair follicle shock. Young men with a full head of hair and who are not at risk of developing male-pattern baldness, or older men who have an established pattern of hair loss, may be candidates for coronal forehead lifts and its modifications. Hair transplantation in conjunction with a forehead lift has been described, allowing for expanded use of a pretrichial incision.

Ptosis

It is of paramount importance for the surgeon to differentiate between lateral eyelid hooding that is a result of upper eyelid skin redundancy and that due to ptosis of the eyebrow. Frontalis contraction must be eliminated by complete patient relaxation to eliminate pseudoelevation of the eyebrows. Patients with eyebrow ptosis will be disappointed with a blepharoplasty procedure without addressing the

brows. Younger patients with ptotic brows and upper eyelid hooding without other signs of upper facial aging often see greater improvements with a forehead lift rather than upper eyelid blepharoplasty. Overaggressive resection of brow or eyelid skin may result in further brow ptosis and a short upper lid syndrome. The effects of the forehead lift/browlift may be demonstrated to the patient by gently elevating the forehead in the midline and laterally. The degree of surgical brow elevation required can be assessed by having the patient actively elevate the eyebrows while the surgeon holds a ruler at a predetermined landmark on the brow. This method allows for the ideal amount of brow elevation to be determined. A slightly greater excision of skin should be made to allow for a degree of stretch-back. For example, about 16 mm of skin may be excised if the real amount of aesthetic lift desired is 10 to 12 mm.

Rhytids

Static and dynamic rhytids should be assessed preoperatively. Assessment of the forehead, glabella, and temple rhytids, along with the relative degree of activity of the upper facial muscles with mimetic expression, helps to determine the extent of myoplasty required for the involved muscles. Older patients typically have more subcutaneous atrophy and thus rhytids are more pronounced due to the actions of the muscles being transmitted more directly to the skin.

Hairline Patterns

Women who have a medium or low forehead hairline are candidates for the standard coronal or endoscopic forehead lift, since both of these will elevate the height of the hairline. Women with higher hairlines most often benefit from a trichophytic lift, which not only maintains their hairline position but also reduces the vertical height of their high forehead. This eliminates the need to style their hair over their forehead to camouflage a high hairline that would result from a standard coronal lift. Older men without evidence of male-pattern balding may be candidates for a standard coronal or trichophytic lift as well.

Skin Type

Fair- and thin-skinned patients usually heal with more ideal scars than those with darker and thicker or sebaceous skin. In general, women scar better than males. Older patients often have finer scars than do younger patients because of their decreased skin elasticity.

Asymmetries

It is documented that 97% of all patients have facial asymmetries (7). Both passive and dynamic asymmetries of the eyebrows should be documented. The surgeon should not try to alter dynamic eyebrow symmetries. Additionally, the surgeon must take caution in an attempt to correct passive asymmetries as this may alter the patient's unique facial characteristics. Even when such attempts are made, the coronal forehead lift and its modification are usually unsuccessful in correcting eyebrow asymmetries because of the distance from the incision to the eyebrows. If such correction is desired, a direct eyebrow or midforehead eyebrow lift are likely to be more successful. Patients with hyperdynamic forehead muscle activity may need more aggressive myoplasties to decrease this degree of activity and minimize recurrence of forehead and glabellar rhytids. This may be achieved surgically or with neurotoxin. The clinical assessment and photographic documentation must be performed with the patient's facial muscles in repose.

Bony Contour

Women with prominent supraorbital rims and excessive forehead bossing may appear masculinized. They may benefit from bone reduction of the supraorbital rim or alloplastic augmentation in association with a coronal forehead lift (8).

PREOPERATIVE COUNSELING

It is imperative to communicate to the patient that brow lifting will have no effect on the eyes other than to improve brow position and lateral hooding. Conversely, upper blepharoplasty will not alter eyebrow position, and if overaggressive skin resection is performed, this may cause further lateral eyebrow ptosis. The lateral infrabrow skin cannot be excised during upper blepharoplasty and, thus, minimal improvement may be achieved in the patient seeking correction of lateral hooding with an upper blepharoplasty rather than with some form of eyebrow lift. Patients should be advised that rejuvenation survey will "turn the clock back" but will not stop the aging process. The patient's specific concerns in conjunction with full facial assessment must be addressed; this is the only way the correct procedures can be chosen. Patients seeking a face-lift should be advised that it will not alter the appearance of the upper face.

MANAGEMENT

During the consultation with the patient, all options—including surgical and nonsurgical options—should be discussed. Surgery may not always be indicated; other methods may be used to correct a specific defect that is of great concern to the patient or to temporize until the patient is a better candidate for surgery. Other such methods include the following:

1. Sun avoidance and protection will prevent photodamage to the skin and help prevent squinting and thus decrease vertical glabellar rhytids.
2. Judicious use of cosmetics may camouflage forehead rhytids.

3. Retin-A cream may increase the vascularity of the skin and the organization of collagen bundles and may thicken the skin, resulting in a more youthful overall appearance and improvement in fine rhytids. It does not improve deeper furrows. Chemical peels and laser resurfacing will provide a greater effect.
4. Styling the hair over the forehead will camouflage rhytids, although it usually cannot camouflage brow ptosis.
5. Injectable fillers may be used selectively for temporary effect in forehead rhytids or furrows and crow's-feet. Fillers have also been used to simulate a brow lift with some success (9).
6. Eyeglasses may camouflage both brow ptosis and glabellar rhytids.
7. Onabotulinumtoxin A (Botox®, Allergan, Inc., Irvine, CA) injections can provide several months of partial muscle paralysis with partial or complete effacement of furrows. Additionally, Botox can be injected into the lateral brows to provide several millimeters of elevation.

All patients should be counseled that the goal is improvement, not perfection. Furthermore, although rejuvenation is achieved, aging continues and cannot be stopped or reversed. Patients will appear younger than if they had not had the surgery but in time will redevelop most of the same features that were improved by the surgery. Patients must acknowledge that a specific result, a "perfect" result, or a no-risk procedure cannot be guaranteed. Each procedure will have specific effects, and patients must be aware of what will and will not be achieved with the procedures they choose. Specifically, patients should be counseled about the general and local complications associated with the procedures they are contemplating, outlining the preoperative, postoperative, and surgical protocols in detail. Literature with instructions and advice about the surgery should be given to the patient, because a well-informed patient can choose the procedure that has the highest likelihood of success for him or her. Of primary importance in forehead rejuvenation procedures are the patient's specific goals, the hairline changes involved, and the acceptability of scar placement.

SURGICAL PROCEDURE AND TECHNIQUE

Surgical rejuvenation of the upper face can be considered within three categories: the coronal forehead lift and its modifications (Fig. 185.5), the direct brow lift and its modifications (Fig. 185.6), and the endoscopic forehead lift. The indications and surgical technique for each of these follow.

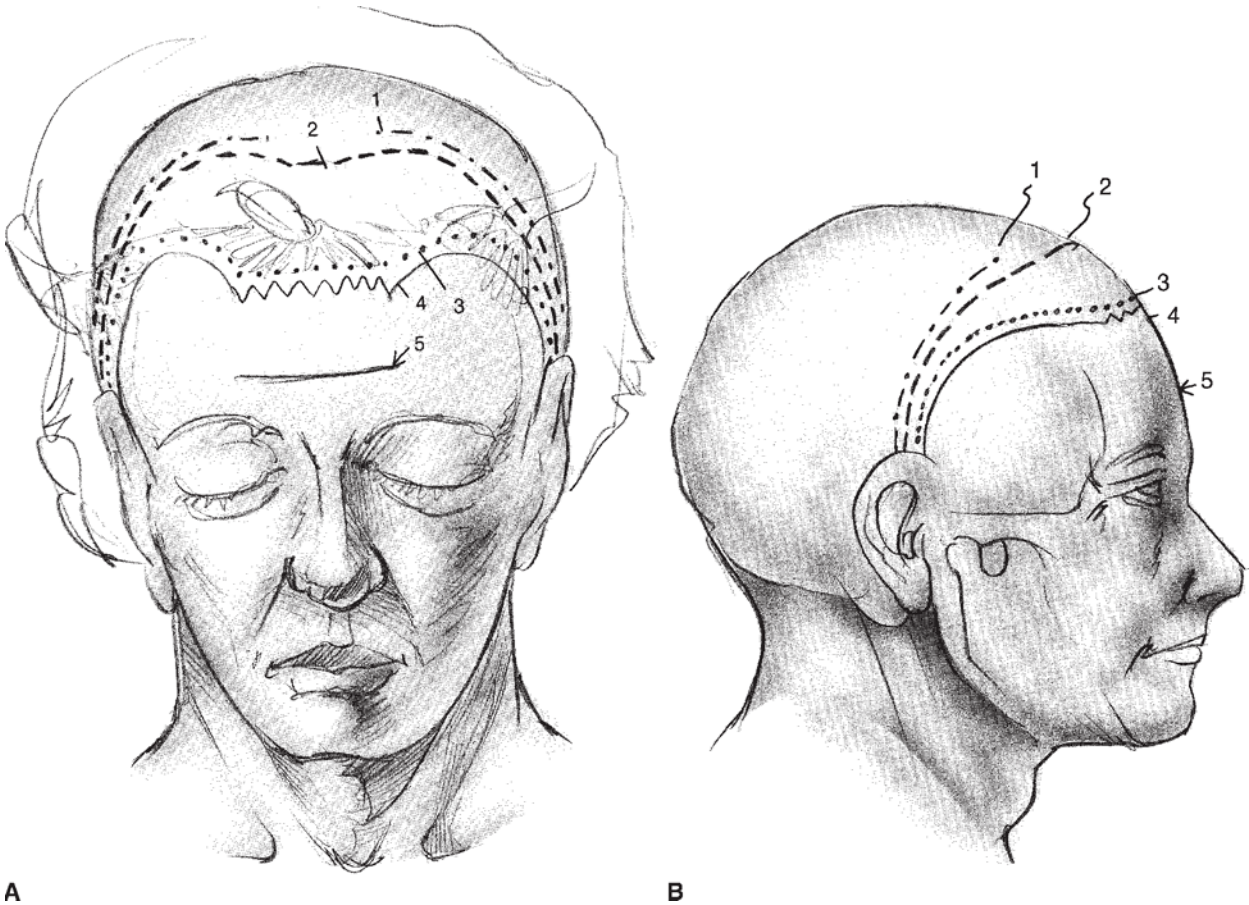

Figure 185.5 The coronal incision is the standard incision. Modifications may be made depending on the patient's hairline, degree of ptosis, rhytids, skin type, asymmetries, sex, and personal preference. **A:** Frontal view. **B:** Lateral view. *1*, Bilateral (temporal); *2*, coronal (forehead); *3*, trichophytic; *4*, pretrichial; *5*, midforehead.

Figure 185.6 The direct brow lift (*solid lines*) is the standard incision. More recent modifications, such as the indirect brow lift (*dashes*) and browpexy (*dots*), can be useful in selected patients.

Coronal Forehead Lift

The coronal lift and its modifications are arguably the procedures of choice for rejuvenation of the upper face. Numerous recent reviews have validated its efficacy, safety, longevity, and high degree of patient satisfaction (2,10,11,12). The coronal lift is especially useful for patients who have both generalized ptosis and rhytids of the upper face and a normal or low hairline (Fig. 185.7). Relative contraindications include men with male-pattern baldness and women with high hairlines. Due to the distance between the incision and the brow, the coronal lift and its modifications are not useful to correct static or dynamic brow asymmetries. Advantages of the open lifts are the well-hidden incision within and behind the hairline and excellent exposure of the forehead musculature, allowing accurate and extensive myoplasty. Disadvantages include elevation of the frontal hairline, although this is an advantage in patients with a low frontal hairline. Other disadvantages include the temporary, and occasionally permanent, hypesthesia or paresthesia posterior to the incision line, although a recent study by Guillot et al. (13) presents good prospective and retrospective data concluding that this may not be a clinically significant disadvantage in the long term. Wide surgical undermining increases the risk for blood accumulation, and tension on the wound closure may predispose to temporary or permanent hair loss, especially if the wound is not meticulously closed in multiple layers.

Technique

The procedure is done under either local intravenous sedation or general anesthesia. General anesthesia is preferable, especially if multiple other procedures are being

Figure 185.7 **A:** Sixty-four-year-old female with a short forehead, brow ptosis, and prominent horizontal forehead rhytids. Note the hyperdynamic elevation of the brows commonly observed in patients with brow ptosis. **B:** One year following coronal forehead lift, upper and lower blepharoplasty, and deep plane face- and neck lift. Note that the brows are now in an improved position without dynamic movement. Note the slight increase in the length of the forehead. **C:** Four years following the above-mentioned procedures—note the longevity of the open forehead lift.

performed (14,15). A curvilinear incision about 4 to 6 cm posterior to the anterior hairline is marked, and a thin strip of hair is removed along the incision line. Local infiltration of anesthesia of lidocaine 1% with epinephrine 1:100,000 and bupivacaine 0.5% with epinephrine 1:200,000 mixed in equal parts is used initially to effect a regional block at the supratrochlear and supraorbital nerves. Following this, a ring block is completed by following the supraorbital margins, the zygomas, and the scalp at the incision site. Infiltration is completed in the subgaleal plane beneath the entire area of the flap to be elevated. At least 7 minutes must be allowed for adequate vasoconstriction.

The coronal incision is beveled parallel to the shafts of the hair follicles, usually obliquely anterior at the midline and becoming more horizontal or even obliquely posterior in the temple region (Fig. 185.8). The flap is elevated with broad scalpel sweeps with a no. 10 blade in the subgaleal plane, abetting this action with firm upward traction on the flap. The pericranium is kept intact and moistened with saline gauze. Prominent vessels may be seen coursing superiorly from the supraorbital vessels about 2 to 3 cm superior to their origin. Scalpel dissection is carried inferiorly to about 1 cm above the supraorbital rims. Dissection laterally must be carried down to the zygoma; this is most safely done with the blade handle and gentle blunt dissection just above the temporalis fascia.

Myoplasty is performed through blunt interfibrillar scissors dissection to identify and free the corrugator muscles from the supratrochlear and supraorbital nerves and vessels, which are multiple and course around the muscle. The flap is dissected over the supraorbital rims, releasing the arcus marginalis, but not so far as to expose orbital fat. In this way the brow is freed so that it may be elevated above the supraorbital rims. The muscle is cauterized with bipolar cautery at two points about 1 cm apart, and the central portion excised. Any bleeding is meticulously controlled with bipolar cautery, taking care not to injure any nerves. The procerus in the midline is identified and incised horizontally using unipolar cautery. The frontalis muscle is identified in the flap, and the unipolar cautery is used to incise the muscle and galea immediately deep to the prominent transverse forehead creases. Cauterization is maintained medial to the pupils to prevent injury to the temporal branch of the facial nerve and also to preserve some natural forehead movement through the action of

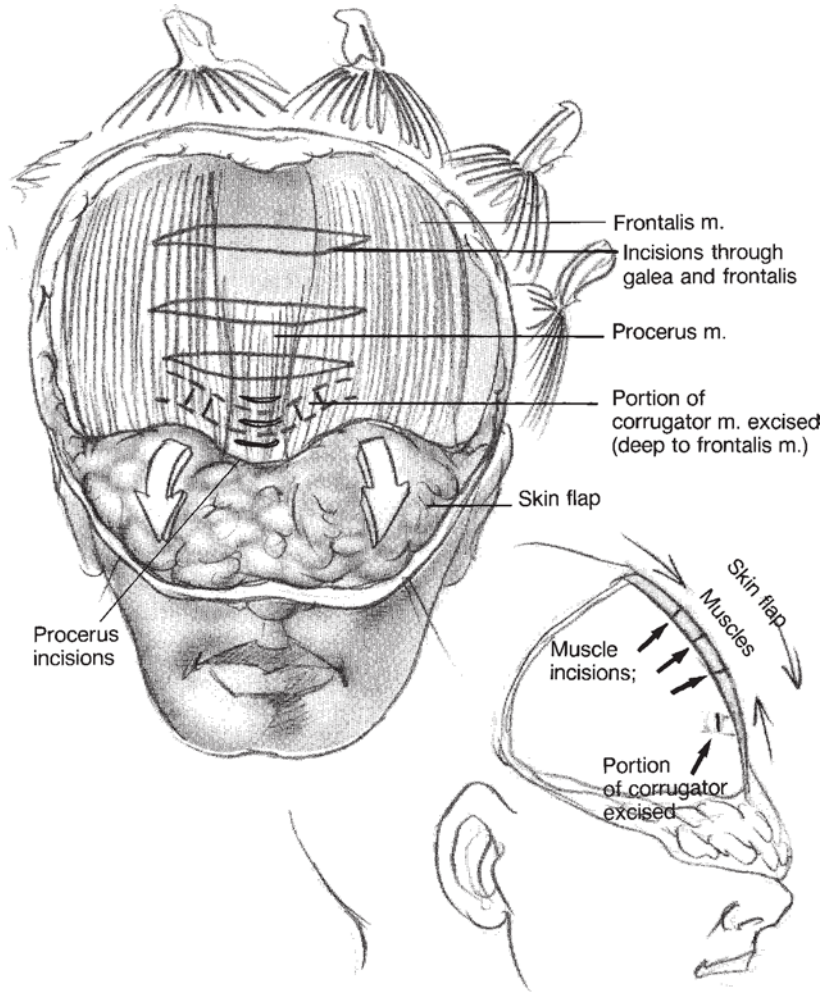

Figure 185.8 The coronal incision is beveled parallel to the shafts of the hair follicles. The flap is elevated over the supraorbital margins and to the zygoma. A portion of the corrugator supercilius is excised, and the procerus and frontalis are incised.

the frontalis muscle laterally. Excision rather than incision of the procerus and frontalis muscles may lead to contour irregularities of the glabella and forehead.

The temporalis branch of the facial nerve is at risk in the region between the brow and the temporal hairline as it traverses this area superomedially. The nerve is deep within the parotid gland but becomes superficial in the subdermal fat as it crosses the zygomatic arch. It then courses deeply again to pierce the frontalis muscle about 2 cm from the lateral canthus (5). The frontalis muscle must not be divided in this region between the eyebrow and the temporal hairline. Absolute hemostasis is secured, paying special attention to superficial temporal artery branches in the supraauricular region. The galeal vessels are cauterized, avoiding bleeding vessels in the subcutaneous tissue so as not to damage hair follicles.

Advancement and rotation of the flap are done in a superior and posterior direction, and the appropriate portion of redundant skin parallel to the hair follicles is excised (Fig. 185.9). This amount can be determined by assessing the amount of brow elevation required and then increasing this by about 5 mm to allow for the stretch-back relaxation that inevitably occurs. Usually, about 12 to 18 mm of skin can be excised, although this will vary with each patient. Conservative excision is indicated to prevent an overelevated and frightened look. In females, more skin may be excised from the temporal region to create a more lateral, feminine lift, depending on the desired correction.

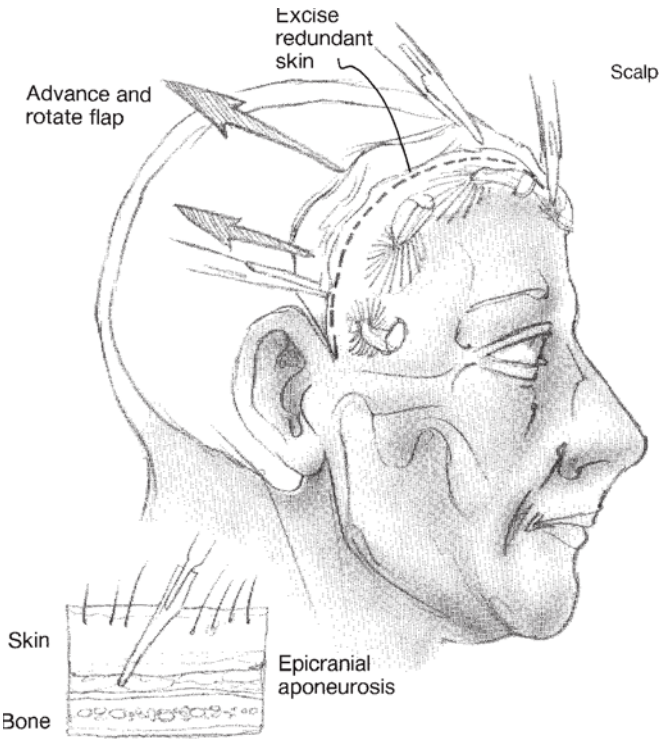

Figure 185.9 The flap is advanced and rotated in a superior and posterior direction, and the appropriate portion of redundant skin is excised parallel to the hair follicles.

The excision usually is extended laterally to 1 to 2 cm above the anterior helical root. A suction drain is placed through a separate stab incision in the temple, the galea is closed by using interrupted and inverted polyglycolic acid sutures, and the skin is closed with staples.

Ophthalmic drops and ointment are prescribed for any indications of corneal exposure. The drain is removed on the first postoperative day, and surgical staples on day 6 and day 8.

Brow Lift and Upper Blepharoplasty

A special relation exists between forehead lifting or brow lifting and upper blepharoplasty. Temporary lagophthalmos is common after brow lifting, and a concomitant upper blepharoplasty will increase the degree and duration of lagophthalmos. The brow lift should be performed first, as a more accurate assessment of the degree of eyelid skin to be excised then can be made. Conservative skin excision is advisable. If no skin must be removed, redundant upper eyelid fat can be excised through a standard excision just above the tarsal plate, taking care not to injure the insertion of the levator aponeurosis.

The eyelid margin should not be above the midpupil after surgery and usually closes within 7 to 10 days. Aggressive postoperative ocular lubrication is necessary until full closure of the palpebral fissure occurs. This is also because the blink reflex initially may be decreased, predisposing to dry eyes.

Eyelid skin can be stored as a graft for up to 3 weeks and used as a full-thickness donor graft to its original site if eyelid closure is unsatisfactory. Patients are advised that a touch-up excision of upper eyelid skin can be performed 9 to 12 months later if necessary, although in our experience this is not usually required or requested.

Patients who have had a previous upper blepharoplasty and require correction of eyebrow ptosis may be candidates for any of the brow-lifting procedures; however, the surgeon must be careful to assess the degree of redundant upper eyelid skin, the status of the tear film, and the amount of skin excised for elevation. Conservatism is advised.

Bilateral Temple Lift and Lateral Brow Lifting

The bilateral temple lift is indicated in men or women who primarily have lateral eyebrow ptosis and upper eyelid hooding. It is advantageous in that it does not elevate the central hairline, as does the full coronal forehead lift and, because of the scar position, can be used in both men and women. However, it does not allow myoplasty procedures of the forehead, and its somewhat confined exposure for elevation makes it difficult to control any bleeding vessels at the supraorbital margin, although increased adeptness with endoscopy has somewhat ameliorated this problem. Although it appears to offer good intermediate-term

results, in our experience it does not appear to offer the longer-lasting results seen with the coronal forehead lift and its variations.

This procedure has essentially the same incision as the coronal forehead lift, except that the incision is carried from just above the anterior helical root up to the midpupillary line, but it does not extend completely across the midline scalp (Fig. 185.5). The incision is beveled parallel to the hair follicles, and a subgaleal dissection is carried out with blunt and sharp scissor dissection down over the supraorbital margin and to the zygoma inferiorly. The temple flap is redraped superolaterally, and the redundant skin excised; it is usually about 10 mm at its widest. The galea is closed with 3-0 polyglycolic acid antitension sutures, and the skin with surgical staples. No drain is usually placed.

The lateral browlift is indicated in patients with a lifelong appearance of downturned lateral brows. In these patients, the lateral brows are ptotic due to the lack of galeal attachment to the supraorbital rim in this region, lateral to the deep temporal fusion line (16). Other patients who may benefit from such a lift are those who suffer from lateral brow ptosis primarily as a result of excess skin.

The procedure begins with an incision 6 cm in length, 1 cm behind the hairline, designed in a curvilinear fashion in the vector of the desired elevation. Two dissection pockets are created—one lateral to the zone of fixation and one medial to it. Laterally, dissection is carried deep to the superficial temporal parietal fascia, just along the surface of the shiny deep temporal fascia. Medially, a subperiosteal pocket is developed blindly down to within 2 cm of the supraorbital rim. The two pockets are then connected from lateral to medial, using a periosteal elevator in a blind motion, sweeping superiorly. The remaining zone of adhesion, which condenses down to become the orbital ligament, is then released down to the orbital rim. The superior and lateral attachments to the superior orbital rim must then be released either with direct visualization or with endoscopic guidance. Dissection laterally is performed similarly to the traditional endoscopic forehead techniques. Fixation can be effected with suture, bone tunnels, titanium screws, or absorbable devices. Excess scalp is excised, and tension-free closure is performed. A drain is not normally placed.

Pretrichial Lift

The primary indication for the pretrichial forehead lift is for women who have a high hairline and long vertical height to the forehead. This procedure then offers all the advantages of the coronal forehead lift but does not raise the anterior hairline to an unaesthetically high level. Furthermore, resection of the redundant forehead skin reduces the vertical height of the forehead, and this often provides improved facial balance. It is best used in women with thick hair who are prepared to wear their hair forward to camouflage the scar in the early healing stages. With scar maturation, no scar camouflage is required in the vast majority of patients (Fig. 185.10). It can be used in men who are not expected to lose more hair or who might be undergoing or willing to undergo hair transplants to camouflage the scar further, although this is rarely necessary as the incision usually heals very well and rarely needs camouflage.

Advantages of the pretrichial lift are that it allows the same wide access to the forehead musculature as the coronal lift and thus allows correction of all the components of the aging forehead. Disadvantages include the necessity for meticulous technique to obtain the finest possible scar and possibility of postoperative scar camouflage being required. A broader area of anesthesia occurs, and usually

Figure 185.10 Anterior forehead hairline 3 months after W-plasty pretrichial incision in a woman.

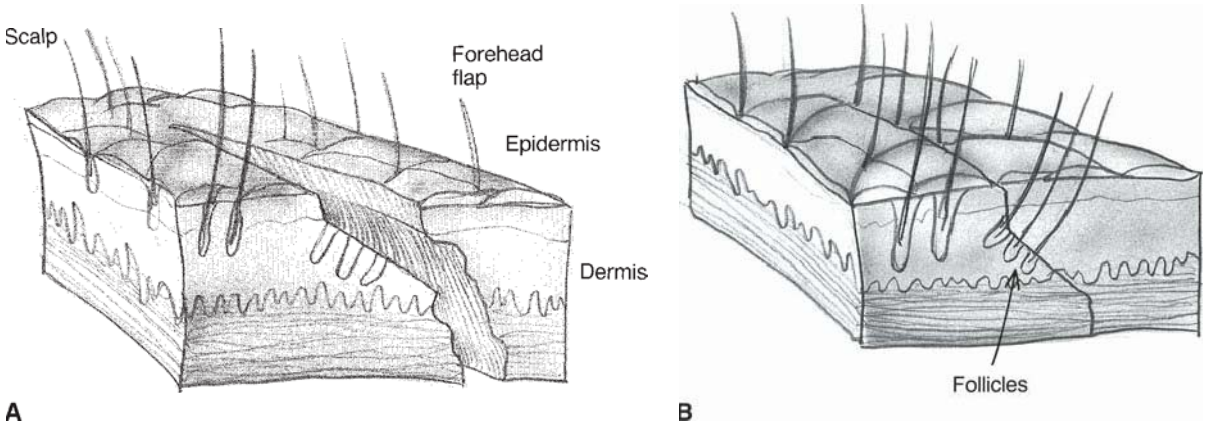

Figure 185.11 **A:** The trichophytic incision is an irregular beveled incision made just posterior to the anterior hairline. **B:** The follicles below the deepithelialized portion of the flap will produce hair growth through the scar.

there is a small permanent area of anesthesia just posterior to the incision. This is rarely a bother to patients, but they must be advised of this possibility preoperatively.

In this modification of the coronal forehead lift, the incision temporally remains the same but is brought anteriorly in the widow's peak region. It then follows a course just behind the anterior hairline as a W-plasty with the limbs about 5.5 mm long and at 55-degree angles that interdigitate with the anterior hairline follicles (Fig. 185.5). The forehead flap is elevated identically to the coronal lift, and myoplasty of forehead rhytids and correction of ptosis are performed. Subcutaneous variations of this lift have been described (17).

Trichophytic Forehead Lift

The trichophytic incision is currently our preferred technique when an open approach is utilized. The incision is a modification of the pretrichial incision; it is placed two or three follicles behind the anterior hairline and is therefore better camouflaged because hair follicles regrow through the scar (Fig. 185.11). It is indicated for women with high foreheads and hairlines and may be considered in men who do not have male-pattern baldness or who would agree to hair transplants should this occur (Fig. 185.12).

The incision is an irregularly irregular beveled incision made just posterior to the anterior hairline (Fig. 185.5). The superficial aspect of the incision is placed down through the epidermis only. Then it is beveled from posterior to anterior through the dermis and subcutaneous tissues to the subgaleal plane. This effectively deepithelializes about 2 mm of the leading edge of the posterior or hair-bearing flap and preserves the underlying hair follicles, although their shafts are excised. After the myoplasty procedures and redraping of the forehead flap, the redundant skin is excised from the non–hair-bearing flap in a parallel beveled fashion to allow the edge of the forehead flap to appose accurately the opposite bevel of the deepithelialized portion

Figure 185.12 Temporal and anterior hairline of a man 3 months after a trichophytic forehead lift. Hair can be seen growing through the incision. By 6 months, this scar becomes almost imperceptible.

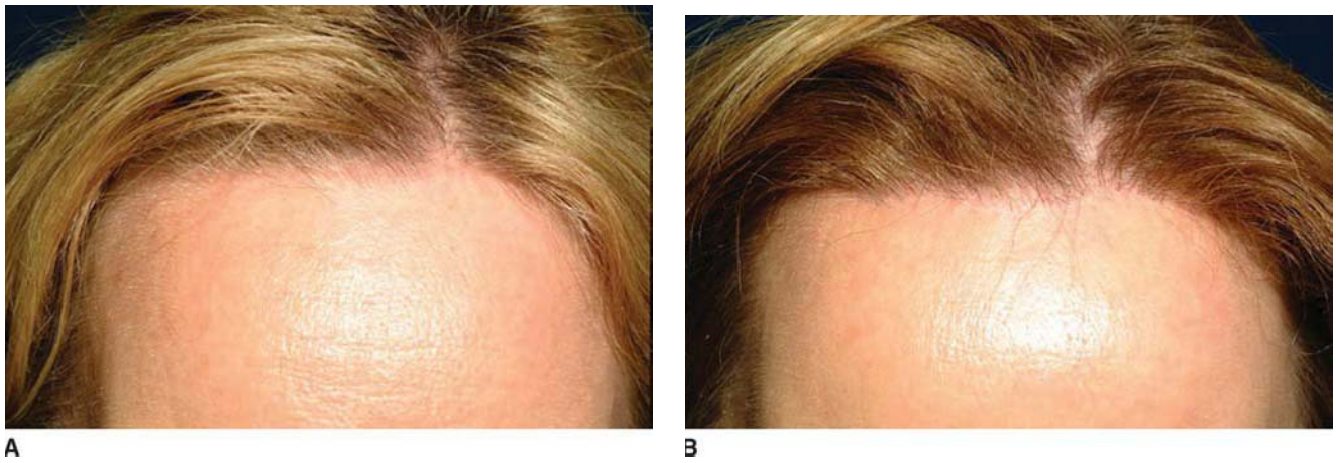

Figure 185.13 **A:** Anterior hairline in a female prior to trichophytic forehead lift. **B:** Anterior hairline in same patient one year following trichophytic forehead lift. This represents an average result with near imperceptibility of the scar. Note that hair is growing through the scar. No neuromodulators were needed following surgery.

of the posterior hair-bearing flap. Galeal sutures again are used for antitension, and the wound is closed with a running 6-0 nylon suture along the forehead skin junction and with staples within the hair-bearing scalp, taking care to prevent damage to hair follicles. With further hair growth from the hair follicles below the deepithelialized portion of the posterior flap, follicles will grow through the scar itself, thus improving camouflage (Fig. 185.13).

The trichophytic incision has the advantage of providing an improved scar but again requires meticulous execution to achieve the desired result. Inaccurate incision placement or wound tension causing strangulation of the hair follicle vasculature will compromise the result. This incision has become the preferred hairline incision. The scar heals so well that most patients can wear their hair back without scar camouflage once healing is complete. Overall, this is the commonest forehead-lifting procedure we employ today (Fig. 185.14).

Midforehead Lift

The midforehead lift, when performed in the central forehead, can be considered a modification of the coronal forehead lift because the dissection can be carried

Figure 185.14 **A:** Fifty-four-year-old female with a high hairline who wanted subtle elevation of brows. **B:** Three years following trichophytic forehead lift, deep plane face-lift, and neck lift.

into the subgaleal plane and myoplasty is possible. This approach is indicated in men with receding hairlines and prominent deep forehead rhytids in which the scar can be camouflaged. The incision is placed in a central midforehead crease, and subcutaneous rather than subgaleal elevation is performed down to the supraorbital margins (Fig. 185.5). This preserves the sensory supply of the forehead, which otherwise would be lost if the midforehead incision were deepened to the subgaleal plane. Access to the corrugator supercilii and procerus muscles is possible by developing a central subgaleal flap inferiorly. Myoplasty can be done if indicated, and the frontalis muscle can be divided between the supraorbital nerves. This approach does not permit the same extent of forehead muscle myoplasty as that in the coronal forehead lift. The inferior flap is redraped superiorly, and the redundant skin is excised to correct ptosis of the glabella and medial eyebrows. If the excision is extended laterally in the subcutaneous plane, some degree of elevation of the lateral eyebrows also can be achieved. In such cases, the procedure is comparable to the indirect brow lift or midforehead brow lift. Advantages of the procedure include a direct and close approach to the glabella without distortion of the hairline. It also allows myoplasty, but it does not offer improvement of the lateral brow region or upper forehead. Its major disadvantage is a potentially unsatisfactory scar and an inability to have a satisfactory lateral brow elevation; this is minimized by making the scar irregular rather than symmetrical, as it follows the crease line. The incisions, and therefore this approach, are usually best in older patients with well-developed forehead creases and thin, nonsebaceous, lighter-colored hair.

Direct Brow Lift

The standard direct brow lift consists of selective excision of skin directly above the eyebrows, combined with suspension of the orbicularis oculi muscle to the periosteum (Fig. 185.15). Brow elevation has also been achieved through a transblepharoplasty approach through an internal brow release, excision of medial brow depressors, with or without placement a of biodegradable fixation device (18,19). This procedure is primarily indicated for men with bushy eyebrows and occasional women who are not candidates for a trichophytic or coronal forehead lift (Fig. 185.16). Because of the direct approach, it is more useful than a coronal lift to correct brow asymmetries and also can be more effective to correct marked ptosis of the lateral eyebrow. It can be used unilaterally to improve facial nerve paresis functionally with suture techniques, biodegradable devices, or with autologous fascia (20). It is relatively contraindicated in patients who have thin, light-colored eyebrows and patients who have thick sebaceous skin that may not scar well.

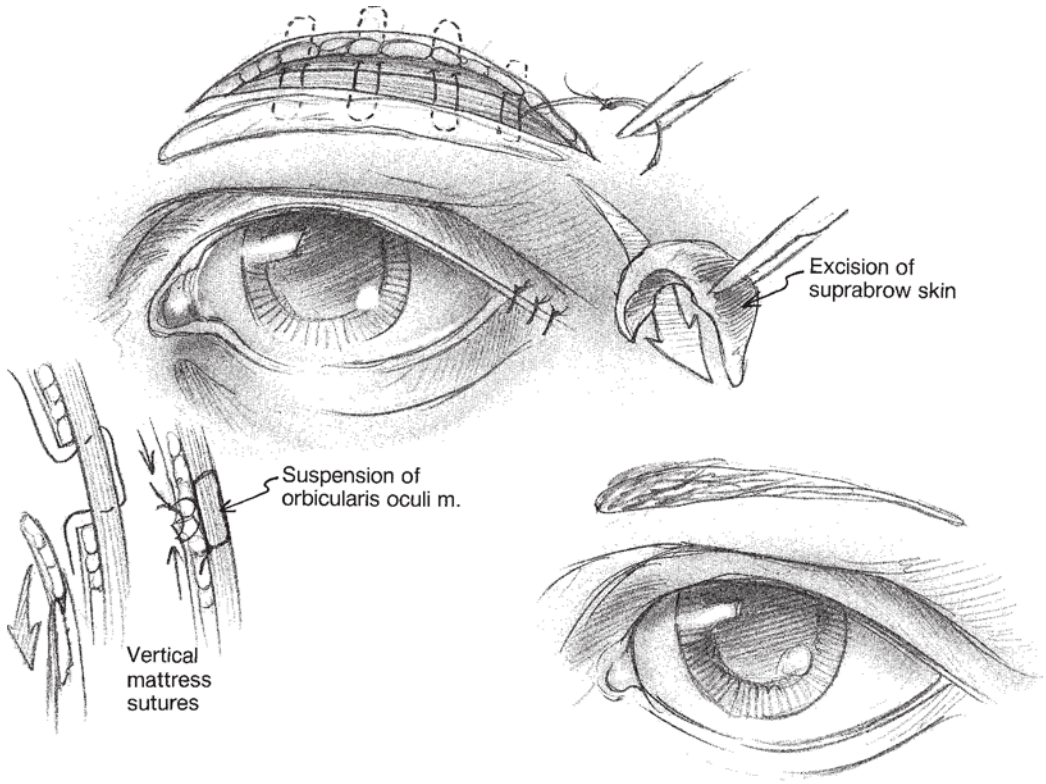

Figure 185.15 Excision of suprabrow skin and suspension of the orbicularis oculi muscle produce direct elevation of the eyebrow.

Figure 185.16 **A:** Sixty-year-old man with eyebrow ptosis, bushy eyebrows, and male-pattern baldness. **B:** One year after direct eyebrow lift and lower lid skin pinch only.

Technique

The inferior incision for the direct brow lift is placed just within the most superior growth of fine eyebrow hairs. It should not extend medial to the medial aspect of the eyebrow, as poor glabellar scarring may result. The incision should be carried lateral to the lateral eyebrow and extended horizontally laterally in a gentle arc, but not superiorly. The superior incision is carried in a gentle arch superiorly from its medial aspect to reach a high point between the lateral limbus and lateral canthus and then gently curved inferiorly to complete the excision. The superior incision defines the new position of the eyebrow, and the point of maximal height will determine the degree of masculinity (apex more medial toward the lateral limbus) or femininity (apex more lateral toward the lateral canthus) of the ultimate brow appearance. The skin is excised down to the subcutaneous plane, taking care not to injure the frontalis muscle or the supratrochlear and supraorbital nerves medially. Usually, a maximum of 10 to 12 mm of skin is excised. Minimal undermining is done inferiorly, taking care not to injure the hair follicles, with 1 to 1.5 cm of undermining in the subcutaneous plane superiorly. Four or five permanent sutures are placed through the orbicularis muscle at the level of the supraorbital margin; then this suspension suture is secured to the periosteum at the level of the superior incision. This latter suture is placed in a horizontal fashion to decrease the risk of injury to branches of the facial nerve. The apical suture is placed first, followed by those medially and laterally. Vertical mattress 5-0 nylon sutures are used for closure and to obtain maximal skin eversion. The sutures are removed on day 4, and light laser abrasion is done, if indicated, 6 to 12 weeks postoperatively—we rarely find this necessary.

Advantages of direct brow lifting include a long-lasting lift as a result of the excellent orbicularis muscle suspension that can be achieved. It is the best technique to correct brow asymmetries or unilateral brow ptosis secondary to facial nerve paresis. More precise positioning of the eyebrow can be obtained than with the more distant coronal lifting, and less dissection is required than for coronal lifting. A significant potential disadvantage is the eyebrow scar, especially in patients who have sebaceous skin or those with thin brows or in whom meticulous technique is not applied. If the incision is not beveled parallel to the hair follicles, the superior aspect of the eyebrow may be lost in time, giving the appearance that the scar has migrated superiorly. Direct brow lifting has no effect on the forehead, glabellar, or temple ptosis and cannot be used to improve forehead or glabellar rhytids. Prominent forehead rhytids may be distorted, giving an unnatural appearance. Meticulous attention must be paid to achieving the ideal bilateral symmetry desired (Fig. 185.16).

Indirect Brow Lift

The indirect brow lift has been associated with the midforehead lift by some authors, and others have called it

the midforehead brow lift (21). It is essentially the same procedure as the brow lift, but the skin excision is performed bilaterally at some distance above the eyebrow in the forehead. The indirect brow lift is indicated in patients with marked or asymmetrical brow ptosis and forehead furrows and those in whom a coronal forehead lift is contraindicated. The patient's skin type must be satisfactory, and the patient must be advised fully about the resultant scar. Men who have male-pattern baldness or women who have thin and light hair with a high hairline are potential candidates.

The surgical approach is similar to that for the direct brow lift, except the inferior incision is placed in a deep rhytid at a distance above the brow, and the superior incision is arched above this. This differs from the midforehead lift, in which the redundant skin is excised from below the initial crease incision rather than above. Undermining the inferior forehead flap must be maintained in the subcutaneous plane down to the supraorbital rims so as not to interfere with sensory or motor innervation. In most cases, the orbicularis muscle is suspended, as described for the direct brow lift.

Advantages of the indirect brow lift include its ability to conceal the forehead incision within a skin crease and at the same time achieve a relatively proximal suspension for the eyebrow, thus leading to a long-lasting and precise elevation. Depending on the location and extent of the skin excision, the shape of the brow also can be configured as desired. Disadvantages include its relatively selective use: it may be indicated in patients who have significant rhytids and skin that will heal well and who are not candidates for a coronal forehead lift.

Browpexy

This procedure is unique in that it is performed through an infrabrow rather than a suprabrow incision (18). It therefore can be used in association with upper blepharoplasty and may negate the need for suprabrow procedures. This procedure may be indicated in the younger woman who is primarily concerned about fullness or puffiness in the lateral portion of the upper eyelids. Other indications are women with mild to moderate eyebrow ptosis and a flatter, androgenous eyebrow appearance. Lateral prominence in the infrabrow region due to a prominent supraorbital margin or brow fat pad also may be improved with this technique. It is particularly useful in association with upper blepharoplasty. Relative contraindications include patients who have severe brow ptosis or more generalized signs of aging of the upper face.

The browplasty is performed first through an upper blepharoplasty incision. Preoperatively, the supraorbital vessels and nerves, which are identified by palpation at their exit from the supraorbital notch and the location of the lateral brow fullness, should be marked. Dissection is extended superiorly 1 to 1.5 cm above the superior and lateral orbital rim in the submuscular plane just deep to the orbicularis oculi muscle. The redundant brow fat pad can be seen overlying the orbital margin; it is removed from the region of the central third of the superior orbital margin laterally as far as the frontozygomatic suture. The fat pad is excised in an elliptical fashion measuring about 1 to 1.5 cm in vertical dimension and tapering nasally and temporally. The underlying periosteum is left intact to prevent adhesions. If brow elevation is not required, the blepharoplasty is completed in standard fashion.

In patients requiring elevation of the central and lateral eyebrow, browpexy is performed to elevate and suspend the brow above the supraorbital margin. The eyebrow position can be fixed superiorly by using two or three permanent 4-0 Mersilene sutures. Each suture is placed transcutaneously at the level of the infrabrow hairs into the sub-brow space and then passed through the periosteum 1 cm above the supraorbital rim. It then is secured through the subeyebrow tissue at the level of the original transcutaneous suture. With tightening of the suture, the eyebrow will be elevated an appropriate amount above the supraorbital margin after the original transcutaneous suture end is drawn through the skin. The placement and tension of each suture can be used to obtain the configuration of the eyebrow and degree of elevation desired. A recent commentary by an experienced oculoplastic surgeon has recommended fixation to the deep temporal fascia laterally to prevent instability of periosteal fixation (22). The blepharoplasty procedure then is completed, removing redundant fat and upper eyelid skin.

Advantages of this technique include the single eyelid incision, which is also compatible with that made for upper blepharoplasty. It allows brow elevation with a more minimal procedure than a coronal forehead lift and allows direct access for trimming the lateral eyebrow fat pad. However, its use is restricted to patients who have only mild to moderate eyebrow ptosis, and the exposure is more difficult compared with direct eyebrow lifting. Removing the eyebrow fat pad transects the cutaneous nerves, resulting in brow anesthesia for several months over this region. Injury to the supraorbital vessels or nerves could result in heavy bleeding or forehead anesthesia. If the suspension suture is placed through the preseptal orbicularis muscle, postoperative dimpling of the thinner eyelid skin and lagophthalmos may occur secondary to eyelid tethering. Inadequate correction of brow ptosis also has been reported.

Endoscopic Forehead Lift

Endoscopic forehead-lifting techniques allow correction of brow ptosis and reduction of forehead and glabellar rhytids (23). The indications for this technique are identical to those for the conventional coronal approaches

A B

Figure 185.17 **A:** A 59-year-old woman with moderate brow ptosis, moderately marked forehead and glabellar rhytids, and moderately high forehead. **B:** The patient 3 years after endoscopic forehead lift, four-lid blepharoplasty, and deep plane face- and neck lift.

(Fig. 185.17). Direct endoscopic visualization affords the ability to identify and preserve the supraorbital and supratrochlear neurovascular bundles, although no more clearly than with the direct approach. Sensory neuropathy and scarring are decreased further because of incision size reduction, change in incision placement, and lack of skin excision in some cases. The reduction in sensory neuropathy may not be as great as was once thought, and a recent prospective and retrospective study has demonstrated that it has not made a significant difference with patient satisfaction (14). The most favorable result can be obtained in the thin-skinned patient with glabellar rhytids, minimal brow ptosis, and minimal skin redundancy. Relative contraindications include women with high hairlines, male-pattern baldness, and some Asians and Native Americans who have tight, thick skin and extensive bony attachments.

Advantages of the endoscopic approach include smaller incisions, decreased incidence of sensory neuropathy and alopecia, less bleeding, and a faster recovery period (10,11,23). Disadvantages involve the need for specialized training and experience with endoscopic techniques with a steeper learning curve than that for the other approaches and the need for confirmation of long-term lift results.

Preoperatively, the location of the supraorbital and supratrochlear neurovascular bundles is identified and marked. The amount of skin advancement to provide an adequate brow lift, usually 10 to 16 mm, is determined and marked with the patient sitting and supine. Glabellar and forehead furrows to be addressed also are marked.

This procedure may be performed with the patient under either general anesthesia or local anesthesia with intravenous sedation, depending on patient and surgeon preferences. Local infiltration with lidocaine 1% with epinephrine 1:100,000 and bupivacaine 0.5% with epinephrine 1:200,000 mixed in equal parts is used in a coronal distribution to provide vasoconstriction before the incision.

The standard endoscopic forehead lift is performed with three to six incisions, which are about 2 cm long (Fig. 185.18). A midline sagittal incision, bilateral paramedian incisions at the level of the midbrow, and bilateral coronal incisions parallel to the hair follicles are placed 1 to 1.5 cm posterior to the hairline. The location of these incisions will vary with surgeon preference. Glabellar rhytid reduction without correction of brow ptosis may be performed without the use of the temporal incisions. Y- to V-advancement flaps can be designed at the incision line if skin excision is desired. The forehead elevation is initiated by extending the vertical incisions through the pericranium. The dissection proceeds in the subperiosteal plane which, because of its decreased vascularity, permits superior visualization. Wide subperiosteal undermining of the scalp is performed in a blind fashion with a periosteal elevator, anteriorly to a level 2 cm above the supraorbital rims

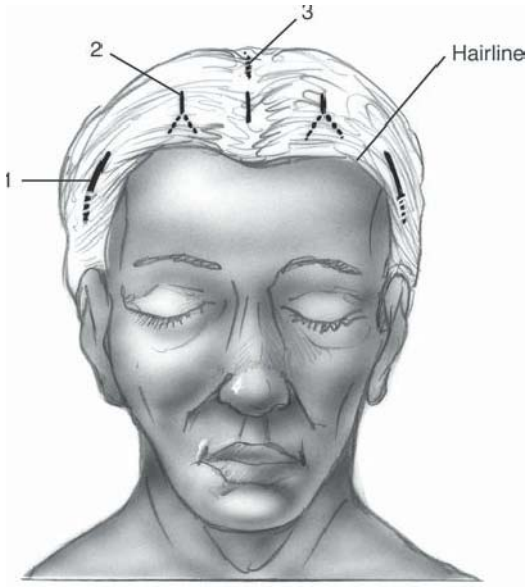

Figure 185.18 The standard endoscopic forehead lift incisions (*solid lines*) are placed 1 cm posterior to the hairline and may vary with surgeon preference. *1*, The temporal incisions may be extended to increase exposure (*dashed lines*); *2*, Y- to V-advancement flaps (*dashes*) will allow for skin excision; *3*, a central posterior vertex incision (*dashes*) provides exposure for miniplate placement.

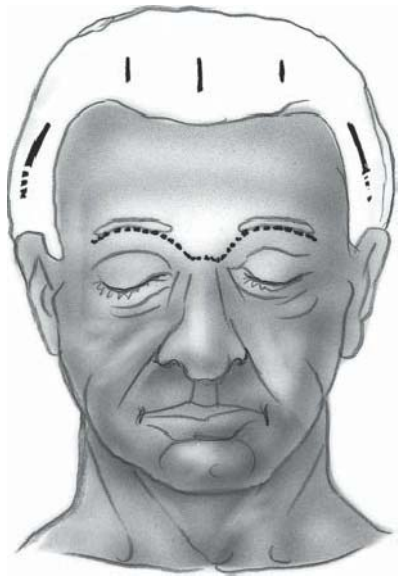

Figure 185.19 The supraorbital dissection is performed with the 4-mm 30-degree scope in the central incision and a small endoscopic elevator in the paramedian incisions. Periosteal relesaing incisions over the orbital margin and blunt elevation down to the zygomatic arch allow for flap advancement.

inferiorly and the temporal lines laterally, and posteriorly to the nuchal line. The supraorbital dissection is performed under direct endoscopic visualization. A 4-mm 30-degree scope is introduced into the central incision, and a small endoscopic elevator is used in the paramedian incisions. The supraorbital and supratrochlear nerves are identified and preserved by using blunt dissection with the endoscopic scissors. The dissection is extended inferiorly over the orbital rims and onto the nasion (Fig. 185.19).

The temporal incisions are extended through the temporoparietal fascia, preserving the superficial layer of the deep temporal fascia. The endoscope and the endoscopic periosteal elevator are used to dissect the lateral orbital rim region inferiorly to the zygomatic arch. The fused fascia planes of the galea, temporoparietal fascia, deep temporal fascia, and periosteum, which insert on the temporal line, are released with sharp dissection. The medial zygomaticotemporal vein, also known as the "sentinel vein," may be encountered 5 to 10 mm lateral to the zygomaticofrontal suture and serves as an important landmark in identifying and preserving the temporal branch of the facial nerve (4,5).

Transverse releasing incisions are made through the periosteum along the supraorbital margin to allow forehead flap advancement. The corrugator and procerus muscles are divided by using the endoscopic scissors. Frontalis muscle division, although not routinely performed, may be performed between the supraorbital neurovascular bundles. Hemostasis is obtained with cauterization.

Flap suspension and fixation are performed after advancement of the flap to predetermined levels. Several different flap-fixation techniques are described in the literature, which include the following: (a) skin staples and taping, (b) microscrew placement in the paramedian incisions of the anterior flap and fixation with skin staples posterior to the microscrew, (c) suspension sutures with cortical microscrew fixation, (d) nylon suspension sutures with fixation to a posterior vertex titanium miniplate, (e) sutures secured through cortical bone tunnels, (f) absorbable screws and cortical anchors (Endotine Coapt Systems, Palo Alto, CA), and (g) fibrin glue (24–28). A surgeon's experience or preference may determine to some degree the method of fixation used. Recent studies, though, will help confirm or deny the scientific merit of some of these techniques. More specifically, fixation methods that rely on temporary means of fixations such as fibrin glue or removable transcutaneous screws are likely to be ineffective according to studies examining the time frame for periosteal adhesion. Perhaps the best study on the subject by Sclafani et al. (29,30) demonstrated that approximately a minimum of 6 weeks is required for adhesion between the cranium and overlying periosteum. An important study by Thomas et al. (31) comparing subperiosteal versus subgaleal dissection in a rabbit model demonstrated that 8 weeks was required for the biomechanical strength of the dissected flap to match undissected controls. Thus, short-term fixation is unlikely to be adequate to maintain brow elevation. Suture fixation

to a microscrew in the anterior flap incision is frequently used. Lateral forehead and brow suspension is obtained with superolateral flap advancement followed by fixation with 2.0 polydioxanone (PDS) sutures from the temporoparietal fascia to the superficial layer of the deep temporal fascia. A subperiosteal drain may be placed although this is not our practice. The scalp incisions are closed with surgical staples. A pressure dressing may be applied. The staples are removed on postoperative day 8 in the office. In general, today the commonly used fixation techniques include sutures with bone tunnels, resorbable fixation devices (i.e., Endotine device), and microscrew/suture cortical fixation.

The incidence of postoperative scarring, alopecia, and sensory neuropathy may be decreased in comparison with those after the standard coronal lift, although a recent prospective study and retrospective review has demonstrated that this does not make a clinically significant difference in objective sensory outcomes or subjective patient satisfaction (13). All other complications are similar to standard coronal-lifting techniques. The amount of forehead lifting that can be achieved and maintained has yet to be consistently confirmed. Although endoscopic forehead-lifting techniques offer distinct advantages, longer-term studies are needed to assess whether the results are comparable to those of the coronal procedures. Recent studies have demonstrated long-term efficacy of both types of lifts, with the most recent literature supporting the role of traditional open brow lifts (2,13–15,31,12).

COMPLICATIONS

Upper facial rejuvenation procedures may be performed with the patient under neuroleptic anesthesia if performed alone or under general anesthesia with more extensive facial rejuvenation procedures. The potential complications associated with any general anesthesia or surgery are present.

Diagnosis of the deformities present in the upper face poses a greater challenge for the surgeon than does that for the lower face. As such, the surgeon must specifically identify both the patient's concerns and the signs of aging that may be corrected by surgery. Such accurate diagnosis will lead to the choice of the most appropriate procedure. Patients must understand exactly what can and cannot be achieved with any given procedure, and their expectations must be realistic. Otherwise, they may be dissatisfied with a satisfactory surgical result. Specific potential complications are discussed in the following sections.

Bleeding

Significant bleeding is rare but may be encountered from the superficial temporal artery in the coronal, pretrichial, or trichophytic lifts or from the supratrochlear or supraorbital arteries in any of these procedures. In the lateral canthal region, bleeding may occur from the zygomaticotemporal artery. Absolute hemostasis with bipolar cautery is recommended. Heavy bleeding can occur from the scalp itself in the coronal forehead lift. We do not use Raney clips but believe that the vasoconstriction achieved with epinephrine in the local infiltration anesthetic is most important. Scalp vessels in the galeal plane should be cauterized, taking care to avoid hair follicles.

Sensory Nerve Injury

Temporary hypesthesia or occasionally hyperesthesia may occur because of irritation of the supratrochlear and supraorbital nerves during flap elevation over the supraorbital margin. In a recent anatomic discussion by Knize, two sites of potential injury to the supraorbital nerve are described: the deep division of the supraorbital nerve is inevitably injured with an initial incision through the galea as it runs just medial to the superior fusion line of the skull and, during subgaleal dissection, the same deep division of the supraorbital nerve may be injured more proximally where fusion between the galea and periosteum occurs at the level of the superior margin of the galeal fat pad (4).

Permanent hypesthesia or anesthesia centrally just posterior to the coronal lift incision, up to 2 cm in diameter, is not uncommon. This is usually of no concern to patients, although they should be advised of this preoperatively. The pretrichial or trichophytic lift will cause a larger area of hypesthesia posterior to the incision line, especially in the short-term period after surgery (14). The browplasty procedure results in temporary hypesthesia over the lateral eyebrow margin for several months.

Motor Nerve Injury

The temporal branch of the facial nerve is at risk primarily in the zygomatic region, probably as much from the infiltration of anesthesia as from surgical dissection. To decrease the risk of injury to this nerve laterally, the central forehead incision of the frontalis muscle should be kept between the pupils. If sharp hooks are used, they must be placed and removed judiciously, especially in the temporal region.

Lagophthalmos

It is most unlikely that lagophthalmos will occur when any of the forehead-lifting procedures is used alone. In the case of either a previous or concurrent upper blepharoplasty, however, it is important to be conservative in excising forehead skin or suspending the eyebrows to prevent inadequate upper eyelid closure, corneal exposure, and possible corneal scarring with visual loss. Inaccurate placement of the suspension sutures through the orbicularis oculi muscle in the browpexy procedure may cause temporary lagophthalmos. In most cases, the gradual resolution of the overcorrected forehead or eyebrows associated with lifting procedures results in resolution of initial mild

lagophthalmos. Patient compliance in using ophthalmic drops and ointment must be obtained in these early phases.

Scar Widening

Scar widening most often occurs in the temporal region, probably as a result of the oblique nature of the hair follicles and inaccurate beveling of the initial or excisional incisions in the coronal forehead lift. Excess tension or excess electrocauterization also may contribute to loss of scalp follicles.

Alopecia

Patients may presume that they are experiencing hair loss if all hair trimmed during surgery is not combed out. True thinning resulting from follicle shock is unusual and often is preceded by a history of alopecia. If a secondary coronal lift is performed with the second incision posterior to the first, hair loss may occur between the two incisions.

Infection

Infection is rare. Its incidence is increased after hematoma development in diabetic patients and in those who have protracted surgery. Patients are covered with a single dose of a broad-spectrum antibiotic 1 hour before surgery. Irrigation of the wound with antibiotic solution can be performed. Treatment consists of incision and drainage and intravenous or oral antibiotics where indicated. If permanent sutures are used for the galeal closure, spitting of the sutures occasionally may occur.

EMERGENCIES

Hematoma

A rapidly expanding hematoma under a forehead flap could compromise vascularity of the flap or at least predispose to significant hair loss. This emergency is typically caused by branches of the superficial temporal artery at the superior helical root but also could occur from the supraorbital or supratrochlear arteries. Immediate elevation of the flap with exploration and cauterization of bleeding sites should be done and a suction drain placed. Intravenous and then oral antibiotics are given to decrease the risk of subsequent infection. A smaller, localized hematoma, as in the glabella or associated with a direct brow lift, may be managed satisfactorily by using incision and drainage, followed by a compression dressing. This is repeated daily until no further recurrence of the hematoma is seen.

Corneal Ulceration

Corneal ulceration is most likely to occur in association with a coronal or direct browlift performed at the same time as an upper blepharoplasty or if the latter was performed previously. Early recognition of exposure due to lagophthalmos is mandatory. Management includes ophthalmic drops and ointment and an eye shield or a tarsorrhaphy if necessary. Early ophthalmologic consultation is indicated.

Nerve Injury

Partial and temporary sensory nerve injuries are not rare when any manipulation is carried out in the region of the supraorbital and supratrochlear nerves, especially during subgaleal dissection at the level of the galeal fat pad (4). Expectant observation is the rule. Frontal nerve injury resulting in partial or complete paralysis of the nerve also requires only hopeful observation; however, firm patient reassurance and frequent follow-up are required in view of the cosmetic nature of these procedures. Should function not return within 3 weeks, nerve studies are performed to confirm the integrity of the nerve and to reassure the patient and surgeon. Long-term management of any residual deformity would include direct brow lifting on the affected side to improve asymmetry in repose.

DISCUSSION

The past few years have seen a tremendous increase in interest in rejuvenation of the upper face. The coronal forehead lift and direct brow lift have undergone numerous modifications to achieve more natural and superior results. This increase in surgical options mandates more accurate attention to deformity diagnosis and procedures selection. Some techniques are specific to a given indication, such as the use of the direct brow lift in a patient with unilateral forehead/eyebrow paralysis. Nonetheless, although clearly many approaches and techniques are used, the most frequently used types of forehead lift by the senior author are the trichophytic and coronal lifts. Although the 1990s and 2000s saw a heightened enthusiasm for minimally invasive and endoscopic approaches, the longevity of these approaches has not been proven in long-term studies. LaFerriere and Perkins (11,23) summarized their experience with the endoscopic brow lift as compared with open forehead lifts by concluding that no difference in the results is apparent. However, more recent analysis of long-term results suggests that the answer is not so clear. Both a national survey by Elkwood et al. (12) and a study by Baker and Chiu (10) in reviewing the results of 21 New York surgeons demonstrated complication rates that were closer to those of the open procedures than previously reported. Another recent prospective study and retrospective review by Rousso (13) demonstrates that although short-term sensory neuropathy is increased with open approaches, long-term results of objective neurosensory outcomes and subjective patient satisfaction are comparable. Johnson and Cilento (2) reported their experience with over 1,000

open browlift procedures and demonstrated excellent patient satisfaction and acceptably low rates of complications. Although a trend toward the increasing use of open approaches and a decline of endoscopic approaches have been noted in experienced facial plastic surgeons, the novice surgeon must recognize the value and utility of the endoscopic approach in the treatment of the aging forehead (32,33). However, it is an acknowledgement that each patient must be assessed as an individual, taking into account the hairline, skin type, degree of rhytids, brow position, and the individual's aesthetic goals before a surgical treatment can be recommended.

Adjuvant treatments also are an important aspect of rejuvenating the upper one-third of the face. Botox has clearly changed how this region is addressed, as it provides excellent effacement of dynamic rhytids and, thus, reduces the need to be as aggressive about performing surgical myoplasty. Filler materials based on hyaluronic acid such as Juvederm (Allergan Inc., Irvine, CA) or Restylane (Medicis Aesthetics, Scottsdale, AZ) provide a longer-lasting option to patients than did collagen, and future materials will likely continue to extend the duration of the efficacy of fillers. Finally, resurfacing techniques, whether they be chemical, laser, or light based (i.e., intense pulsed light), provide a solution to the finer rhytids of the skin. Skin surfacing serves to be synergistic with the effects of surgical treatments to the forehead. As resurfacing modalities continue to improve, so will the final results we will be able deliver to our patients.

HIGHLIGHTS

- The eyebrow is the key landmark in forehead aesthetics. Its passive and dynamic characteristics, gender differences, and changes with aging are important factors in selecting the appropriate rejuvenation procedure.
- The major categories of lifting procedures for upper facial rejuvenation are the coronal forehead lift, endoscopic forehead lift, and the direct eyebrow lift.
- Modifications of each have specific indications.
- The most commonly used techniques today are the trichophytic forehead lift, endoscopic lift, and direct brow lift.
- Accurate diagnosis of each patient's specific complaints and findings is needed so that the correct procedure can be chosen.
- The resultant scars should be explained in detail so that the patient can help choose the ideal procedure.
- A complete ophthalmologic examination is required for patients who have had previous upper blepharoplasty or in whom an upper blepharoplasty is to be performed concomitant with forehead or brow lifting. Specific attention to dry-eye problems and conservative surgery are indicated.
- All incisions must be made to maintain hair follicle integrity and to avoid the first branch of the trigeminal nerve and the frontal branch of the facial nerve.
- For long-lasting results, elevation of the forehead flap over the supraorbital margin and galeal suspension are required. In direct brow-lifting procedures and their modifications, the orbicularis oculi muscle must be suspended to the periosteum.
- To maintain a smooth forehead contour, incise rather than excise the procerus and frontalis muscles.
- When redraping, overcorrect to allow the inevitable stretch-back.
- Forehead procedures may be indicated in patients who are not usually considered candidates, including young women who have premature ptosis of the eyebrows and men who do not have male-pattern baldness or are candidates for hair transplants.
- Botox and fillers, especially hyaluronic acids, are excellent nonsurgical tools for rejuvenation of the aging forehead.

186 Upper Eyelid Blepharoplasty

Jonathan M. Sykes *Christina K. Magill*

Upper eyelid blepharoplasty is a common and often straightforward procedure; however, there are multiple considerations that need to be applied to each patient having surgery of the upper eyelid in order to ensure safety and optimal results. It is critical that the patient's underlying concerns and pathology are identified prior to surgery. A patient who desires cosmetic upper eyelid blepharoplasty must be counseled appropriately about realistic expectations, recovery time, and the details of elective surgery. The older patient who presents primarily with a complaint of decreased vision must be properly diagnosed: is there a change in visual acuity or ocular insult? Is *brow ptosis* or *blepharoptosis* contributing to the problem? Is the peripheral loss of vision primarily from excessive upper eyelid skin, also known as *dermatochalasis*? A proper assessment of the patient's desires and applied anatomy will maximize surgical outcomes and minimize complications. Success in upper eyelid blepharoplasty is guided by an understanding of surgical anatomy, patient motivational and medical history, the use of preoperative photography, appropriate surgical technique, and avoiding potential complications. This chapter outlines the preoperative considerations and surgical techniques for upper eyelid blepharoplasty.

SURGICAL ANATOMY

To perform upper eyelid blepharoplasty, a thorough understanding of the upper eyelid–brow complex, cross-sectional anatomy of the upper eyelid, and anatomic composition of the eyelid crease is necessary (Fig. 186.1) (1). The eyebrow and the upper eyelid skin constitute the *upper eyelid–brow complex*. The upper eyelid–brow complex moves the eyelid during expression and serves a functional role. The frontalis muscle acts on the brow as an elevator, and the orbicularis oculi acts on the brow as a depressor during eye closure and facial expression. When evaluating the eyebrow, it is important to evaluate brow height, inclination, and orientation (2). The brow lies along the supraorbital rim in men in a relatively straight position. In women, the hair of the brow arches above the superior orbital rim at its lateral extent. As individuals age, the frontalis muscle can become atrophic and lax, allowing the brow to descend. In some patients, placing a finger on the eyebrow and returning it to its more youthful position may correct excess upper eyelid skin or loss of peripheral vision that would not be corrected with upper eyelid blepharoplasty alone (3).

In addition to evaluation of the upper eyelid–brow complex, an understanding of the tissue layers of the upper eyelid is critical to successfully perform upper eyelid blepharoplasty. There are several tissue layers in the upper eyelid, which are (from superficial to deep) skin, *orbicularis oculi muscle*, *orbital septum*, *preaponeurotic fat*, the *levator aponeurosis*, *Müller muscle*, and the *tarsus* and *conjunctiva*. A sagittal section of the upper lid can help illustrate the levels and depths of the upper lid retractors, fat compartments, and the tarsal plate (Fig. 186.2) (1).

The sectional anatomy of the upper eyelid begins with the skin. The upper eyelid skin is the thinnest skin in the body and is less than 500 microns thick. The skin of the upper eyelid is the thickest superiorly and the thinnest at the ciliary margin. Excess upper eyelid skin is often what patients wish to be surgically corrected.

Beneath the thin upper eyelid skin is the orbicularis oculi muscle. This muscle has a radial, sphincter-like pattern around the eye and is considered part of the *superficial musculoaponeurotic system*, mainly innervated by the zygomatic branch of the facial nerve. The muscle acts to close the eye, narrow the palpebral opening, and squint. The lateral ocular rhytids, or smile-lines that can appear in the skin over time, are perpendicular to the underlying orbicularis oculi muscle. The orbicularis oculi muscle can be very thin and easily incised along with the skin incision. Conversely, the orbicularis oculi muscle can also

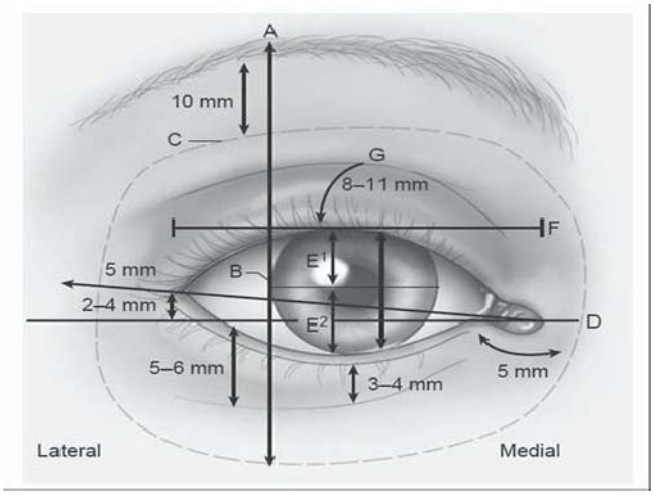

Figure 186.1 Topographic anatomy of the eyelids and eyebrow. (A) A vertical line drawn tangent to (B) the lateral limbus demarcates the highest point of the eyebrow. The inferior hair-bearing line of the eyebrow typically rests 10 mm above the superior orbital rim. (C) The orbit boundaries. (D) The lateral canthus is positioned 2 to 4 mm superior to the level of the medial canthus. (E^1) The MRD_1 is measured from the upper eyelid margin to the corneal light reflex at the level of the pupil. (E^2) The lower eyelid margin measured to the corneal light reflex is the MRD_2. The intrapalpebral distance is measured as MRD_1 + MRD_2 and ranges from 9 to 12 mm. (F) The palpebral width ranges from 28 to 30 mm. (G) The upper eyelid height ranges from 8 to 11 mm, depending on gender and ethnicity. (Adapted from Most SP, Mobley SR, Larrabee WF Jr. Anatomy of the eyelids. *Facial Plast Surg Clin North Am* 2005;13(4):487–492.)

Figure 186.3 Orbicularis oculi muscle hyperfunction. Static and dynamic excess eyelid squeeze are shown.

be hypertrophic, causing lid thickening and excess eyelid squeeze (Fig. 186.3).

The tissues that lie deep to the orbicularis oculi vary from superior to inferior and include the frontal bone, orbital septum, and tarsal plate. At the level of the brow, the orbicularis oculi muscle is superficial to the frontal bone and the superior orbital rim. Inferiorly, the orbicularis oculi muscle lies superficial to the orbital septum above and the tarsus below. Three surgical designations of the orbicularis oculi exist according to the tissue beneath the muscle: there is an *orbital*, *preseptal*, and *pretarsal* portion (Fig. 186.4) (4). The fibrous tarsal plate is approximately 8 to 9 mm in height and acts as a skeletal component that shapes and supports the arch of the lid. In addition, the tarsal plate contains *meibomian glands* at its inferior border. There are several layers of the upper eyelid that fuse and insert onto the tarsal plate, including the orbital septum and upper eyelid retractors.

The orbital septum begins superiorly at the superior orbital rim as a reflection of the frontal bone periosteum.

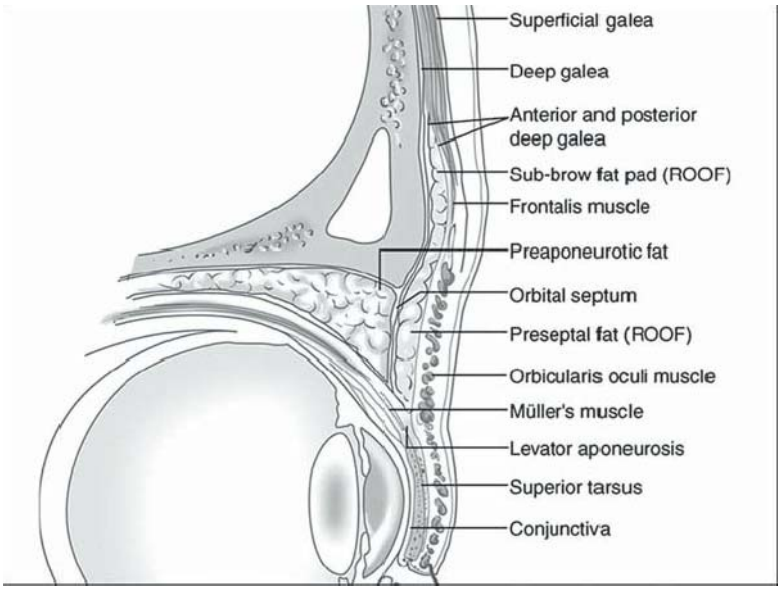

Figure 186.2 Sagittal section through orbit and upper eyelid. The superficial to deep anatomy of the upper eyelid is demonstrated. The thin upper eyelid skin overlies the orbicularis oculi muscle. Deep to the orbicularis oculi muscle is the orbital septum, which contains the preaponeurotic fat. The upper eyelid retractors are beneath the fat pad and consist of the levator aponeurosis and Müller muscle. (Adapted from Most SP, Mobley SR, Larrabee WF Jr. Anatomy of the eyelids. *Facial Plast Surg Clin North Am* 2005;13(4):487–492.)

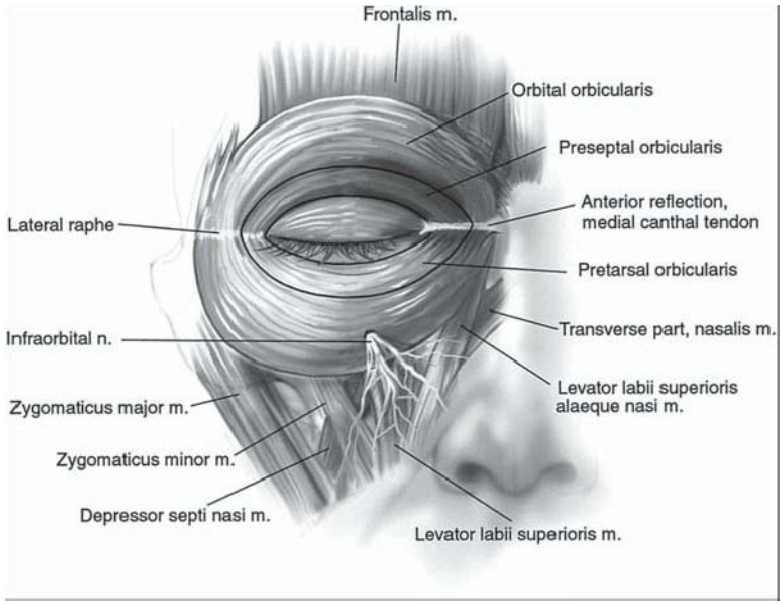

Figure 186.4 Periorbital musculature. The orbital, preseptal, and pretarsal segments of the orbicularis oculi muscle are shown. The frontalis muscle inserts at the level of the supraorbital rim and acts to elevate the eyebrow. (Adapted from Codner MA, Ford DT. Blepharoplasty. In: Thorne CH, et al, eds. *Grabb and Smith's plastic surgery*. 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2007.)

This reflection of the septum orbitale is called the *arcus marginalis*. The orbital septum has a white appearance (in contrast to the pink color of the orbicularis muscle) and acts as a barrier to infection. As the orbital septum becomes lax with age, underlying fat can prolapse anteriorly and inferiorly, and this can cause visible bulges beneath the thin eyelid skin.

The orbital contents contained by the orbital septum include preaponeurotic fat and the lacrimal gland. The preaponeurotic fat includes a medial fat pad and a central fat pad (Fig. 186.5) (4). The fat pads, in addition to the lacrimal gland, can all descend as the orbital septum connective tissue relaxes with aging. The prolapse of fat can create bulging beneath the thin upper eyelid skin (5). The preaponeurotic fat pads can also become prominent in *blepharochalasis*, a condition marked by intermittent eyelid edema.

Deep to the preaponeurotic fat are the muscular upper eyelid retractors. The upper eyelid retractors include the *levator palpebrae superioris muscle* (levator muscle) and *Müller muscle*. The primary upper eyelid retractor is the levator muscle, which is suspended by the superior transverse (*Whitnall ligament*). Whitnall ligament extends from the fascia of the lacrimal gland laterally to the trochlea attachment medially. The ligament conceptually suspends the levator muscle and allows it to change directions (Fig. 186.6) (4). As the levator muscle descends from its superior condensation with Whitnall ligament, it becomes a thick aponeurosis that inserts onto the anterior face of the fibrous tarsal plate. The elevation of the tarsal plate by the levator muscle is controlled by motor fibers from the oculomotor nerve (cranial nerve III).

In contrast to the levator muscle, Müller muscle is an involuntary smooth muscle lid retractor that receives

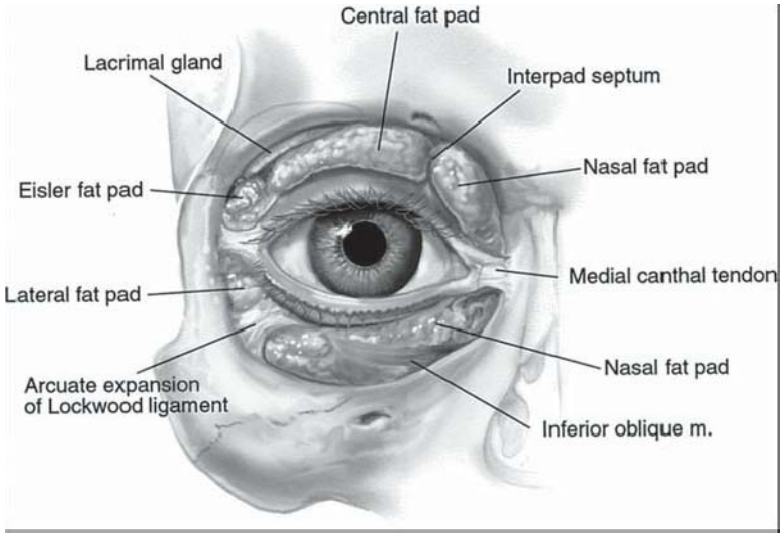

Figure 186.5 Postseptal orbital compartment. The nasal fat pad, central fat pad, and lacrimal gland are shown deep to the orbital septum. Prominent fat pads can be conservatively excised during upper eyelid blepharoplasty. (Adapted from Codner MA, Ford DT. Blepharoplasty. In: Thorne CH, et al, ed. *Grabb and Smith's plastic surgery*. 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2007.)

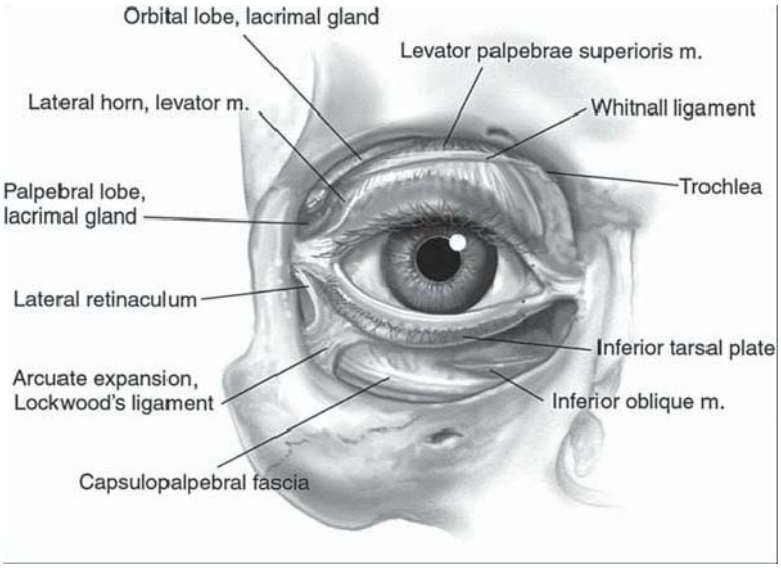

Figure 186.6 Orbital suspensory attachments. The levator palpebrae superioris muscle is shown as it descends from Whitnall ligament to the anterior face of the tarsal plate. (Adapted from Codner MA, Ford DT. Blepharoplasty. In: Thorne CH, et al, ed. *Grabb and Smith's plastic surgery*. 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2007.)

sympathetic innervation. When sympathetic tone is absent, such as in *Horner syndrome*, the eyelid is noticeably ptotic by 2 mm. During dissection in the postseptal compartment of the upper eyelid, Müller muscle is found beneath the levator aponeurosis. An arcade of vessels travels on the anterior surface of Müller muscle.

The deepest layer of the upper eyelid is the conjunctiva, a clear mucous membrane that provides lubrication and protection to the sclera. The conjunctiva consists of a *tarsal* component that lines the undersurface of the eyelids, *fornix*, the apex of the orbit/eyelid junction, and a *bulbar* component that adjoins the sclera of the globe. Preserving the conjunctiva helps protect against corneal damage.

A component of the periorbital anatomy that deserves special mention is the composition of the upper eyelid crease. In Caucasian individuals, the upper eyelid crease is formed as the levator aponeurosis inserts onto the anterior surface of the tarsal plate, approximately 2 to 5 mm from its superior border, and has further insertions into the overlying skin at this level. Visually, these insertions create a fold in the upper eyelid that is usually 8 to 11 mm above the lid margin in women and 6 to 9 mm above the eyelid margin in men. In contrast to the Caucasian upper eyelid, the Asian eyelid has a crease that is much closer to the eyelid margin due to the orbital septum fusing with the levator aponeurosis above or at the level of the tarsal plate (Fig. 186.7) (6). With this difference in orbital septum insertion, in addition to lower or absent skin attachments, the fold of the upper eyelid obscures a prominent crease in the Asian eyelid.

EVALUATION

Motivational History

Patients who seek upper eyelid blepharoplasty generally have functional problems or aesthetic problems. Often, both functional and aesthetic issues coexist. It is important to identify the goals and concerns of the patient in order to formulate the correct treatment plan.

In the patient who presents with a complaint of decreased vision, the consultation should begin with a thorough history of the problem. Patients who suffer from brow ptosis or dermatochalasis associated with aging often recount a gradual loss in their peripheral vision. Some patients will report that when they lift up their eyelids or eyebrows, they can see normally again. For other patients, visual acuity may be so poor at baseline that no manipulation of the periorbital skin improves their visual fields. For these patients, the risks of surgery may outweigh any benefits. As the visit proceeds, four patient assessment questions must be answered: (a) What is the brow position? (b) Is there any upper eyelid ptosis? (c) What is the baseline visual acuity? (d) Is the patient a candidate for elective surgery?

In addition to visual complaints, patients request upper eyelid blepharoplasty for aesthetic reasons. Communication with patients desiring a change in the appearance of their upper eyelid is of paramount importance. It is essential to understand what the patient's expectations are from the procedure and to manage these in such a way that a realistic outcome is conveyed and understood. Patients may desire a removal of excess skin or fat, or an alteration in the shape or position of the upper eyelid crease. The extra time devoted to managing the expectations of a cosmetic patient is always time well spent.

Medical History

It is important to obtain a thorough preoperative medical history. For patients undergoing blepharoplasty, it is important to evaluate for any underlying connective tissue or bleeding disorder that will affect the outcome of the surgery or lead to poor results. Patients need to be asked

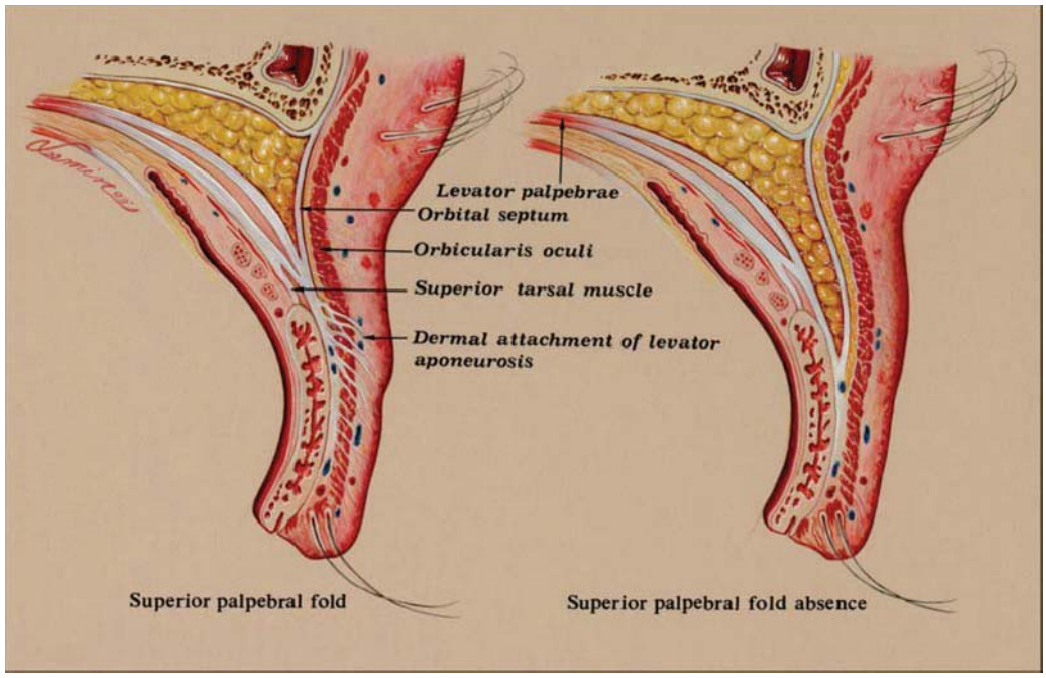

Figure 186.7 The upper eyelid crease. Anatomical variations can result in the absence of the upper eyelid crease. On the left, a sagittal section represents the Caucasian upper eyelid, with dermal attachments extending from the levator aponeurosis to the skin, resulting in an upper eyelid crease. On the right, the lower insertion of the orbital septum on the levator aponeurosis and lack of extensions into the dermis result in the absence of the upper eyelid crease. (Adapted from Chen SH, Mardini S, Chen HC, et al. Strategies for a successful corrective Asian blepharoplasty after previously failed revisions. *Plast Reconstr Surg* 2004;114(5):1270–1277.)

about a history of bleeding with prior surgeries and blood pressure control and asked to stop any elective anticoagulant medication 5 days prior to the operation. Any herbal medications known to have an anticoagulant effect must also be stopped 2 weeks prior to surgery. Patients must discontinue supplements containing vitamin E, ginkgo, fish oil, garlic, and any substance that may pose extra risk. A smoking history is also important to obtain, as cigarette smokers are at higher risk for poor wound healing.

An ocular history must also be included in the evaluation of a patient seeking blepharoplasty. This includes any previous eye surgeries, refractive eye surgery, and a history of glaucoma, cataracts, or ocular trauma. If the patient has a known "dry eye syndrome," this is also important to note, as this may place them at higher risk for postoperative corneal abrasion and serious eye exposure problems. Patients who have undergone a previous blepharoplasty will have expectant scar tissue and mandate a conservative approach to avoid excessive *lagophthalmos* or scleral show.

Physical Exam

Upper blepharoplasty is an elective procedure. Any physical exam of a patient desiring blepharoplasty should begin with a global assessment of the patient's general health and well-being, and the examiner should draw a conclusion about the patient's candidacy for elective surgery. The physician should assess the character of the facial skin and global changes of aging. It is also important to note the solar changes of the skin and to note any suspicious skin lesions over the face that may warrant further attention. The physical exam should proceed with evaluation of visual acuity and a neurologic exam. Following this, a periocular exam should be done, including an evaluation of symmetry, brow position, eyelid skin, upper eyelid height, fat prolapse, and levator function. As one examines each of these factors, a treatment plan can be formulated.

Assessing visual fields and visual acuity are an important part of the preoperative exam. Patients will often report a change in their visual fields from drooping of the brow or upper eyelid. Documenting visual field changes is important prior to upper eyelid blepharoplasty. A superior visual field loss of 20% or 15 degrees is often required for insurance coverage. Patients can undergo visual field testing in a neutral position and then with their eyelids or brows suspended upward with tape to document potential gains from the surgery. Methods of visual field testing can include using an automated visual field technique or tangent screen technique in which a patient is seated 3 feet from a target that is advanced closer to the patient until it comes into view for the tested eye. These exams can be done in conjunction with the patient's ophthalmologist (7).

The patient's vision prior to surgery may determine their candidacy for elective upper eyelid blepharoplasty. If a patient is legally blind or has dismal visual acuity at the time of consultation, the functional improvements from

performing the surgery may be nominal. Any previously undiagnosed or undocumented changes in visual acuity or baseline vision should be formally assessed by an ophthalmologist prior to any elective surgery.

Along with an assessment of vision, the patient should undergo a standard neurological exam, with attention to pupillary reaction and extraocular muscle function. Lid tone and movement should be carefully examined, with care to note any ptosis, or the presence of poor eyelid closure or scleral show from a weakness in the facial nerve. Sensation of the eye can be tested by performing a corneal reflex exam.

In addition to an assessment of vision and a neurologic evaluation, a periocular exam is done to formulate a treatment plan for the patient and identify what pathology is present. A periocular exam includes the evaluation of symmetry, brow position, quality of the eyelid skin, upper eyelid height, fat prolapse, and levator function.

Upper eyelid symmetry is important aesthetically and functionally. The surgeon can strive to measure and create symmetric upper eyelid height and to create bilateral scars that are of equal length and position. The patient and surgeon should discuss facial asymmetries before surgery and understand that baseline asymmetries may persist after the operation.

As part of the periocular exam, the brow position needs to be carefully noted. In men, the maximal point of brow height should occur in the midpupillary line, and the brow should be oriented relatively straight along the superior orbital rim. In women, the maximal brow height should occur at the level of the lateral limbus, with the brow lying slightly above the superior orbital rim and having a temporal arch. Noting the brow position helps to diagnose what changes and underlying conditions are contributing to a patient's decrease in peripheral vision or what is causing them to have excess skin laxity of the upper eyelid. If raising the brow to its natural anatomic or youthful position improves an individual's visual fields or cosmetic complaints, the patient may benefit the most from a brow lift alone or a brow lift in conjunction with upper eyelid blepharoplasty.

Following an exam of the brow, the quality of the upper eyelid skin is assessed. Excess and atrophic skin is common in the senile upper eyelid. The removal of redundant skin should not alter the position of the upper eyelid margin. Conversely, some patients may have limited upper eyelid skin, a preexisting condition causing lagophthalmos, or scleral show. Removal of skin in these patients may cause problems associated with corneal exposure.

An assessment of the upper eyelid height and crease is an important part of the periocular exam. The upper eyelid can be obscured by excess skin, can have an absent crease, or can be excessively long or blunted. The ideal upper eyelid crease height is 8 to 11 mm in women and 6 to 9 mm in men. In patients who have an absent crease, such as in the Asian eyelid, the underlying orbital septum may insert at the superior edge of the tarsus, or low along the tarsal border, and the levator aponeurosis may lack any dermal attachments (Fig. 186.7). These anatomic relationships can be altered surgically to create a crease. An excessively long or blunted crease can be a result of underlying ptosis, previous blepharoplasty, or loss of fat and periorbital volume.

The periorbital fat can bulge and prolapse beneath the thin upper eyelid skin as the orbital septum weakens with age. The removal of fat depends on the patient's anatomy and the goals of the operation. A "hollowed" look can often result from overaggressive fat excision. In contrast to the lower eyelid, which has a medial, central, and lateral fat compartment, the upper eyelid has only a medial and central compartment, with the lateral space occupied by the lacrimal gland. Any one of these compartments, and the lacrimal gland itself, may contribute to the appearance of excessive skin and volume descent in the upper eyelid. The assessment of prolapsed fat and possible asymmetries between the upper eyelid fat compartments should be noted with the patient preoperatively, and expectations and goals should be clarified.

In addition to fat prolapse, the position and mobility of the eyelid margin needs to be examined. It is important to assess any level of upper eyelid ptosis and the levator function in all patients undergoing upper blepharoplasty. Many patients who desire upper blepharoplasty or are referred for decreased central and/or peripheral vision will suffer from blepharoptosis (ptosis). The otolaryngologist needs to know how to assess both the degree and amount of ptosis and the function of the levator mechanism. In broad terms, ptosis is an abnormally low upper eyelid margin with the eye in primary gaze. Ptosis can be either congenital, in which the levator muscle usually does not function properly, or acquired, in which the levator aponeurosis has become dehiscent, or has lax insertions to the anterior tarsal plate. In acquired or involutional ptosis, the muscle will still function, but will not provide the level of lid lift to accommodate the patient's visual fields.

The physical examination for ptosis and levator function begins with a measurement of the relationship of the upper eyelid margin to the central corneal light reflex. A penlight can be used to create the reflex, and a measuring tape can be used to assess the *marginal reflex distance* (MRD_1), or the distance between the edge of the upper eyelid and the reflex. In patients without ptosis, a normal measurement for this is approximately 4 to 5 mm. The distance between the optimal eyelid level and the actual level is the amount of ptosis. The MRD_2 is the distance from the lower eyelid margin to the central corneal reflex, and it is by adding the MRD_1 and MRD_2 together that the opening of the eye or *palpebral fissure* can be measured. The average palpebral fissure will measure approximately 9 mm.

Activation of the levator muscle results in retraction of the upper eyelid, with a resultant increase in the palpebral opening. Levator function can be measured by holding the

eyebrow in place to isolate the eyelid retractors and asking the patient to close the eye or look down, followed by performing an extreme upgaze (Fig. 186.8). A measuring tape can be used in the extreme upgaze position to document the distance between downgaze and upgaze. The maximal excursion of the upper lid, or levator function, is normally greater than 15 mm. Levator function between 12 and 15 mm is considered good, and less than 9 mm of function is poor. If the levator function is abnormal, a diagnosis other than acquired/involutional ptosis needs to be considered, and the differential diagnosis includes an extended list of neurological, autoimmune, neoplastic, endocrine, genetic, and connective tissue disorders. The assessment of levator function and the diagnosis of ptosis is a critical part of the

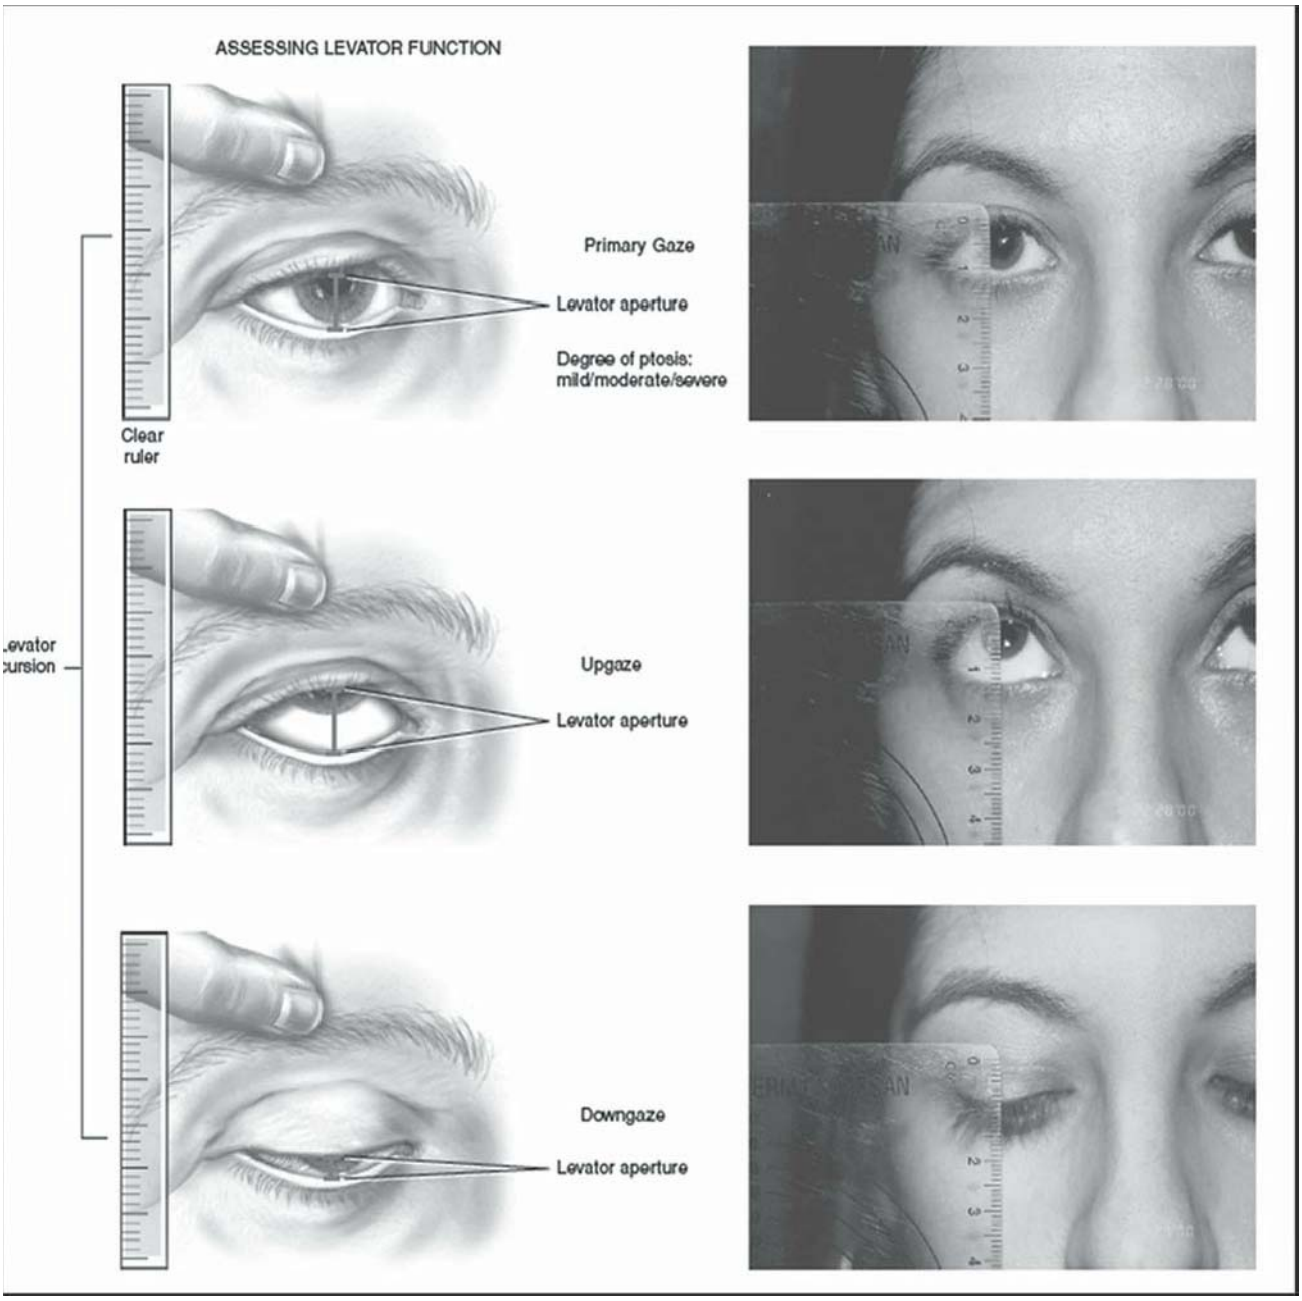

Figure 186.8 Testing levator function. In order to correctly diagnose and treat the underlying cause of ptosis, levator function is assessed. This is done by measuring the palpebral aperture in neutral position, downgaze, and upgaze. The maximal excursion of the upper lid, or levator function, is normally greater than 15 mm. (Adapted from Newman ML, Spinelli HM. Reconstruction of the eyelids, correction of ptosis, and canthoplasty. In: Thorne CH, et al. eds. *Grabb and Smith's plastic surgery*. 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2007. From Spinelli HM. Ptosis and upper eyelid retraction. In: Spinelli HM, ed. *Atlas of aesthetic eyelid and periocular surgery*. Philadelphia, PA: Elsevier, 2004:96.)

ocular physical exam. The surgical correction for ptosis is markedly different than simply performing an upper eyelid blepharoplasty and may involve reinsertion of the levator aponeurosis onto the anterior surface of the tarsal plate to achieve the desired result.

PHOTOGRAPHY

Preoperative photography not only aids the surgeon in devising the operative plan but may also be a prerequisite for insurance carriers. Photographs should include a frontal view of the face, in addition to standard lateral and oblique views. Close-up photos of the eyes in open and closed position help to document skin excess and fat prolapse, in addition to palpebral fissure and levator function. There are often preexisting asymmetries in the eyelids and periorbital fat that are obscured after the infiltration of local anesthetic, and preoperative photographs help to document these.

THE OPERATION

Every eyelid surgery should preoperatively define what the goals are, which may be to remove extra skin, change the skin contour, address excess muscle, remove or transpose fat, elevate the level of the upper eyelid margin, or alter the upper eyelid crease. The surgical techniques employed are organized around the goals. Upper eyelid blepharoplasty will not correct asymmetric brow or brow ptosis, lateral ocular rhytids or "crow's-feet," malar or cheek fat pad descent, or fine lines and wrinkles around the eye. These complaints can be addressed with a brow lift, the use of selective botulinum toxin (Fig. 186.9), midfacial or malar implants, deep plane facelifts, or skin resurfacing.

Surgical Technique

In patients who have the chief complaint of skin excess, the amount of extra skin removed is determined by a patient's anatomy. A 12-mm height of infrabrow skin needs to remain intact to allow adequate eyelid closure and to avoid eyelid margin malposition. The upper eyelid crease can be marked in the preoperative holding area or with the patient sitting up to achieve the greatest accuracy. The surgical markings should start with a central mark above the pupil at the level of the desired upper eyelid height. A second mark is made in the midpupillary line, directly above the initial mark which will determine the amount of skin removed. Between these two points is skin to be excised. It is critical that at least 20 mm of skin is left from the upper lid margin to the brow line or superior orbital rim in order to avoid lagophthalmos and preserve independent upper lid movement from the frontalis muscle.

After the two central marks are made, an ellipse is drawn out with medial and lateral limbs. The medial and lateral limbs should be checked for distance from the upper eyelid margin, so that the distance along the inferior aspect of the incision stays relatively equidistance from the upper eyelid margin. A medial upcut or lateral triangulation can be included in the marking, according to surgeon preference, in order to aid in cosmetic closure. The lateral extent of the skin marking should remain medial to the lateral orbital rim and can be placed in a rhytid. After completing the skin markings, it is important to reexamine each mark for symmetry and to assure that adequate skin will remain after the skin excision is completed. It is at this time that moderate modifications of skin markings should be made. The patient can be asked to open and close the eyes to assess the markings for accuracy and symmetry (Fig. 186.10).

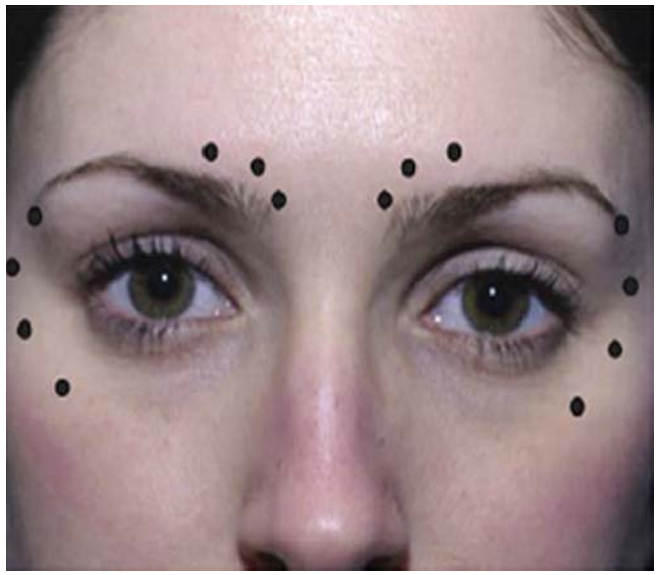

Figure 186.9 Sites of botulinum toxin injection for periocular rejuvenation. The *black dots* signify potential injection sites for botulinum toxin to treat glabellar rhytids and "crow's-feet," which are not addressed by surgery of the upper eyelid. (Adapted from Hetzler L, Sykes J. The brow and forehead in periocular rejuvenation. *Facial Plast Surg Clin North Am* 2010;18(3):375–384.)

Monitored anesthesia care and local anesthetic are adequate for most patients undergoing upper eyelid blepharoplasty. The eyelid skin can be injected with 1% lidocaine, 1:100,000 epinephrine loaded into a 1-mL syringe with a 30-gauge needle. The tip of the needle is gently inserted into the upper eyelid with the goal of injecting between the skin and the muscle to avoid a hematoma. Small aliquots of local anesthetic can be delivered in the area to be excised, and pressure can be held over the injected area with gauze. The upper eyelid skin is very thin, and the injection should be very shallow. Approximately 1 to 1.5 mL of local anesthetic is injected into each upper eyelid.

Following the injection of local anesthesia, the patient is prepped and draped while the surgeon scrubs. The entire face should be included in the surgical field. A head wrap is placed, and the neck is toweled off. Because the upper eyelid skin is thin and lax, it can be difficult to make accurate incisions. For this reason, tension and countertension

on the skin must be made by the surgeon and assistant to facilitate precise skin incision. The surgeon stands or sits at the patients head and makes the lower incision first with an assistant providing gentle countertraction on the upper lid. The skin incision can be made with a scalpel which provides clean wound edges. The upper limb is then incised, with an assistant providing gentle inferior countertraction on the area to be excised. If needed, the medial and lateral corners can be completed with scissors at the beginning of the dissection. After the skin is incised, the lateral corner of the incision is grasped with fine-tipped forceps. Using scissors, a plane directly beneath the skin is established. In addition to grasping forceps, the long finger of the nondominant hand can be used to provide medial pressure on the skin to be excised in order to facilitate the development of the proper plane. As the skin excision reaches its medial extent, a small upcut can be made at the corner of the ellipse to facilitate skin redraping for the closure (Fig. 186.10).

Figure 186.10 Operative technique in upper eyelid blepharoplasty. A right upper eyelid surgical marking is shown. There is a minimum of 12 mm of infrabrow skin preserved. Marking of the upper eyelid precedes the injection of local anesthestic, which is shown in the middle image. The strip of upper eyelid skin is then sharply excised **(bottom image)**, with care to preserve the underlying orbicularis oculi muscle.

In addition to the removal of skin, some patients may also need a strip of muscle excised. Many authors think that minimal or no muscle should be removed because muscle excision can cause dysfunction of the orbicularis oculi. However, in rare instance, muscle can be hypertrophic, causing excess squeeze on the upper eyelid and thickening (Fig. 186.3). In these cases, a strip of muscle can be removed.

Patients may have prolapsed upper eyelid fat pads that need to be addressed. Fat excision is accomplished after the excision of skin and begins with identifying the orbital septum. The orbital septum is beneath the orbicularis oculi muscle and contains the medial and central fat pads. A conservative approach is advised in order to avoid an aged or hollow appearance. The orbital septum can be opened over the fat pad of interest. The orbital septum is thin and pale and can be difficult to identify in some patients. If there is doubt about the location of the orbital septum, it is best to work superiorly instead of inferiorly to avoid damage to the levator aponeurosis at the level of the tarsus. Gentle pressure can be placed on the globe to exaggerate fat prolapse and identify the fat to be excised. The septum can be delicately teased off of the enderlying fat pad. The fat can be gently mobilized inferiorly and also superiorly toward the superior orbital rim. The central fat can be dissected off of the underlying levator aponeurosis. The fat pad is often covered by a delicate, thin capsule. This can be incised to reveal prominent yellow fat tissue. Patients will often require further injection with local anesthetic during this portion of the case. The base of the fat to be excised should be cauterized to avoid retraction of bleeding tissue. It is important not to remove all of the visible fat pad and to avoid excess traction on the fat as it is excised. This traction can cause trauma to deep vessels which may retract and later cause intraorbital hematoma. Traction on the orbital fat also misleads the surgeon into thinking deeper orbital fat needs resection. To remove fat from the medial compartment, the orbital septum can be opened medially with care to avoid the medial palpebral artery, which can cause brisk bleeding.

The levator aponeurosis lies beneath the orbital fat, and this can be repositioned in patients who desire a change in lid margin height or in the creation of an upper eyelid crease. For patients with involutional ptosis, whose upper eyelid margin is encroaching over the aperture of the pupil, the elevation of the upper eyelid may markedly improve vision. This is accomplished by identifying the preaponeurotic fat beneath the orbital septum and gently reflecting this superiorly. The levator aponeurosis will be visible under the fat, as a thickened, white condensation of muscle that travels inferiorly toward the tarsal plate. The patient can be asked to open the eye to confirm its location, as it will retract superiorly. At this point, if the levator aponeurosis is dehiscent from the tarsal plate, it can be reattached using medial, central, and lateral 4-0 Vicryl sutures. The suture can be thrown in a horizontal mattress fashion from the edge of the aponeurosis, to the anterior

upper third of the tarsal plate. It is important not to pass any suture deep through the conjunctiva. The amount of lid elevation can be confirmed before the suture is secured by asking the patient to open the eye and examining the amount of distance achieved from the pupil and lid margin. The levator aponeurosis can also be sutured to the deep dermis at the level of a desired upper eyelid crease in Asian upper eyelid blepharoplasty (Fig. 186.11).

After all aspects of the upper eyelid blepharoplasty have been performed, the incisions are closed (Fig. 186.12). Due to the very thin nature of the upper eyelid skin, healing is usually rapid and results in a minimally visible scar. Despite the various type of surgical closures and suture materials, upper blepharoplasty incisions result in excellent scars. The overarching goal of closure is to facilitate good wound healing with a low risk of dehiscence and visible scar. The closure will create the neo-lid crease and can be done with a 7-0 nylon running suture with minimal grasp of the wound edges by the suture. Any areas of questionable strength can be reinforced with an interrupted stitch. Alternately, the wound can be closed with a running 6-0 fast gut suture with a central interrupted 6-0 suture placed for extra insurance against dehiscence. The suture line can be very delicate, and too much manipulation postoperatively can lead to wound problems. Patients are advised to avoid rubbing the eyes and to abstain from vigorous physical activity in the postoperative period. Ice can help with bruising and swelling.

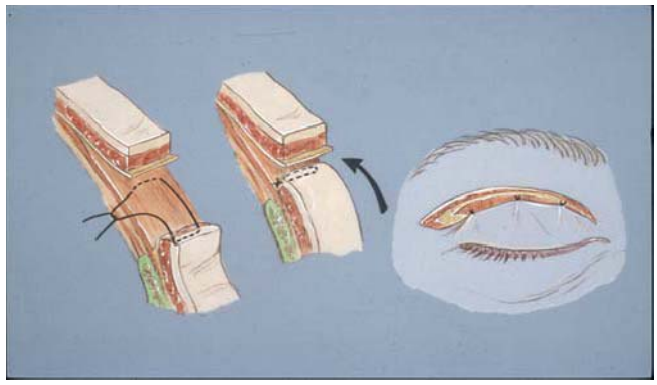

Figure 186.11 Creation of an upper eyelid crease. A sectioned upper eyelid is shown on the far left. The skin, orbicularis oculi muscle, and orbital septum have been dissected away from the levator aponeurosis. A horizontal mattress stitch has been placed superiorly in the levator aponeurosis and inferiorly in the deep dermis. In the middle image, the suture has been tightened. The image on the far right demonstrates the formation of the new upper eyelid crease after suturing.

Figure 186.12 Preoperative and postoperative photographs after blepharoplasty. **(Top)** Preoperative frontal and oblique views of the eyes are shown, demonstrating dermatochalasis and global changes of aging. **(Bottom)** There is youthful restoration of the periorbital skin following bilateral upper and lower blepharoplasties.

COMPLICATIONS

Complications of upper eyelid blepharoplasty are rare and include bleeding, infection, and the need for revision surgery (8). Asymmetry between the two upper eyelids is the most common complication, and this is best avoided with careful preoperative markings. Preexisting asymmetries in lid position or brow position may contribute to postoperative asymmetry. The interruption of the orbicularis oculi can occasionally contribute to corneal exposure problems, which usually resolve as the muscle regains functionality. In the interim, corneal protection can include the use of eye lubricants and gentle massage. The presence of corneal exposure from lagophthalmos can be the result of over aggressive skin excision, which is especially problematic in revision upper blepharoplasty or in patients with known dry eye syndrome. In extreme cases, this can be treated with skin grafting, but at the expense of an ideal cosmetic result. Blindness following upper lid blepharoplasty is extremely rare and can result from postoperative hematoma formation. If recognized in a timely fashion, it may be possible to evacuate the hematoma and restore vision.

In managing and diagnosing complications, it is important that the patient have easy access to medical care and examination. The patient should be counseled about what is normal after surgery and what is not normal. It is expected that the patient will experience tenderness at the surgical site and some blurry vision from any ointment used. Abnormal postoperative events would be for the eye to swell shut, for pain to be severe, or for there to be any true vision change or loss.

CONCLUSION

Upper eyelid blepharoplasty can be a very rewarding operation for the surgeon and patient, alike. It is critical to properly diagnose any underlying brow descent or ptosis prior to upper blepharoplasty in order to offer patients the correct surgical treatment for their complaint. Taking a careful preoperative history and performing an attentive physical examination is important to ensure good outcomes. The expectations of the patient must be clearly understood and managed. Careful diagnosis and attention to detail will help avoid any untoward complications and minimize patient dissatisfaction.

Lower Eyelid Blepharoplasty

187

Stephen W. Perkins *Jess Prischmann*

Lower eyelid blepharoplasty is one of the most common and technically challenging procedures in facial plastic surgery. Unlike upper eyelid blepharoplasty, surgery on the lower eyelid has a lower threshold for error and a higher potential for complications. Most blepharoplasty surgeons will encounter unexpected postoperative outcomes. Because of this, an intimate understanding of anatomy, methodical evaluation of patients, obsessional intraoperative treatment of tissue planes, and prompt recognition of complications are required for success in this detail-driven and rewarding procedure.

LOWER EYELID ANATOMY

The upper and lower eyelids contain analogous structures. Knowledge of upper eyelid anatomy begets understanding of its lower counterpart.

The eyelids are divided into lamellae. The anterior lamella is composed of skin and the orbicularis oculi muscle. While the skin of the eyelid is the thinnest in the body, the thickness of the orbicularis is variable. The posterior lamella is composed of the tarsal plates, capsulopalpebral fascia, and palpebral conjunctiva. The capsulopalpebral fascia is part of the lower eyelid retractor and is an extension of the inferior rectus muscle. The middle lamella refers to the orbital septum (Fig. 187.1).

The lower eyelid is critical in creating a natural "almond" shape to the palpebral fissure. It is most commonly angled slightly upward, with the lateral canthus being 2 mm higher than the medial canthus. Variations exist, as the palpebral fissure can be angled downward or neutral. The lower eyelid margin should rest at the inferior limbus of the iris. Maintaining these topographical relationships is important in blepharoplasty.

The lower eyelid has three described fat pads: medial, central, and lateral. The inferior oblique muscle separates the medial and central fat pads. The central and lateral fat pads are separated by the arcuate expansion of Lockwood ligament. The medial fat pad is most commonly transposed to efface the "tear trough deformity" (as described below).

The inferior oblique muscle can be vulnerable to injury during lower lid blepharoplasty. It originates from the orbital floor lateral to the nasolacrimal canal. It takes a posterolateral course, passes inferior to the inferior rectus muscle, and inserts on the globe. Injury to the inferior oblique can result in a range of disability, from transient diplopia to permanent strabismus. This complication can largely be avoided by only transecting fat that protrudes anterior to the orbital septum (1).

The blood supply to the lower eyelid is through rich anastomoses between the internal and external carotid artery systems. The major arteries include the dorsal nasal, angular, infraorbital, transverse facial, zygomaticofacial, and medial palpebral. From a surgical perspective, the plane between the orbital septum and orbicularis is relatively avascular. However, meticulous hemostasis is required when dissection proceeds anteroinferiorly (as performed in fat transposition) or posteriorly (as performed during routine access to fat pockets).

The sensation to the lower eyelid is from branches of the infraorbital nerve, a terminal branch of the maxillary division of the trigeminal nerve. The motor innervation is through the oculomotor and facial nerves.

IMPORTANT TERMINOLOGY

Knowledge of a few basic terms is required for effective communication with regard to lower eyelid blepharoplasty.

Orbital fat pseudoherniation or palpebral bags: Bulging of orbital fat that is seen in conjunction with a weakened orbital septum and/or relaxation of Lockwood ligament. Visible pseudoherniation of orbital fat disrupts the normally smooth transition between the eyelid and cheek subunits and creates an "aged" or "tired" appearance.

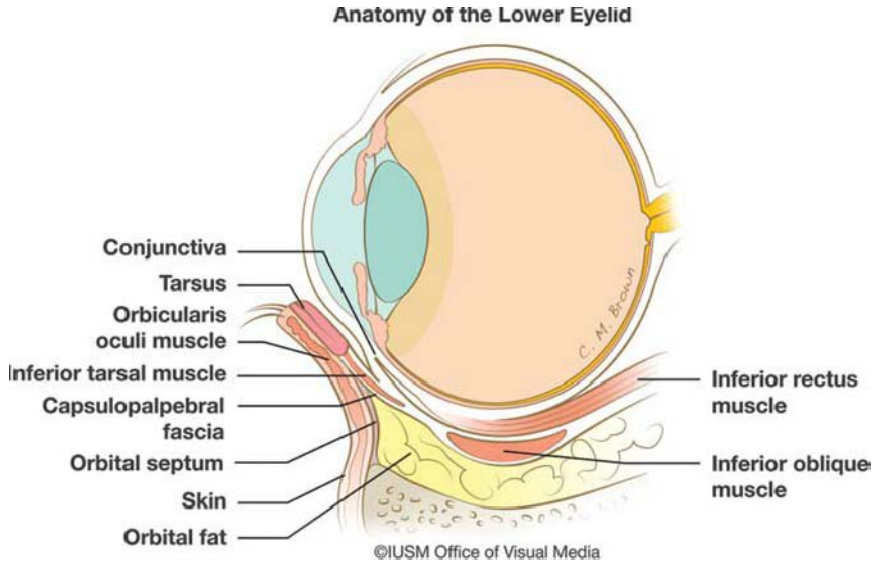

Figure 187.1 Anatomy of the lower eyelid.

It is considered to be the most common indication for lower eyelid blepharoplasty (Fig. 187.2).

Dermatochalasis: Excess skin of the eyelid (Fig. 187.3). Dermatochalasis should not be confused with "blepharochalasis," which is a rare inflammatory disorder of the eyelids characterized by recurrent edema.

Orbicularis hypertrophy: Increased thickness of the preseptal or preorbital portions of the orbicularis oculi muscle (Fig. 187.4). This sign is often mistaken for orbital fat pseudoherniation.

Scleral show: The measurement of white (sclera) show between the inferior limbus of the iris and the margin of the lower eyelid when the head is in the Frankfort horizontal plane (Fig. 187.5).

Negative vector: Seen when the anteriormost point of the cornea projects beyond the inferior orbital rim. Most commonly recognized on profile view (Fig. 187.6).

Lower eyelid laxity: Horizontal excess of the lower eyelid that occurs as the result of aging. Clinically determined by the snap and/or distraction tests (Fig. 187.7).

Ectropion: Outward turning of the eyelid margin away from the globe (Fig. 187.8).

Entropion: Inward turning of the eyelid margin toward the globe.

Tear trough deformity: The soft tissue surface depression seen along the medial inferior orbital rim, often accentuated by orbital fat pseudoherniation (2) (Fig. 187.9).

Double convexity deformity: The contour deformity that results from descent of the suborbicularis oculi fat pat below the arcus marginalis and weakening/bowing of the orbital septum above the arcus. Most commonly seen on three-quarters or profile view. This deformity is considered an indication for fat repositioning in lower eyelid blepharoplasty or midface lift (3) (Fig. 187.10).

Festoons: Redundant folds of lax skin and orbicularis muscle that hang in a hammock-like fashion from canthus to canthus (4) (Fig. 187.11).

Malar mounds or bags: The soft tissue convexity seen between the orbicularis retaining ligament and the zygomaticocutaneous ligament. As aging occurs, the "fixed"

nature of the ligaments causes a visible disruption in the contour between the eyelid and cheek (Fig. 187.12).

PATIENT SELECTION AND EXAMINATION

The ideal lower eyelid blepharoplasty patient is healthy, has reasonable expectations, and presents with findings easily correctable with a surgical procedure. In order to determine appropriate candidacy, the surgeon must be prepared to look for and elicit for pertinent signs and symptoms.

An evaluation should always begin with an assessment of the patient's motives and expectations. Lower lid blepharoplasty can correct orbital fat pseudoherniation, excess skin and muscle, mild festooning, and tear trough deformities. However, if the patient's main concerns include abnormal skin pigmentation, fine rhytids, or large malar bags, the surgeon must explain that a blepharoplasty is not the appropriate procedure (5) (Fig. 187.13A and B).

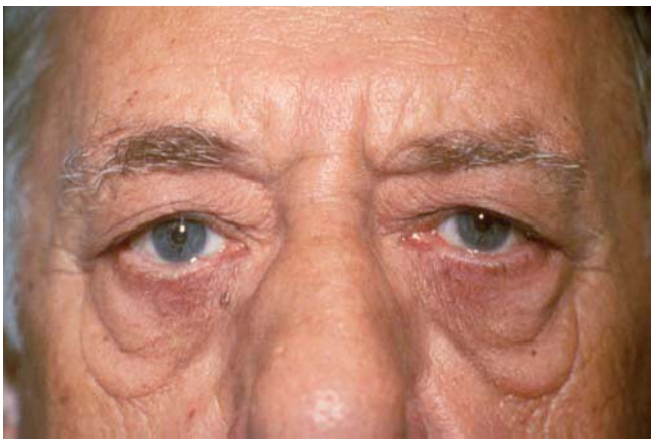

Figure 187.11 Lower eyelid festoons.

Figure 187.12 Malar mounds. This finding is not easily correctable with standard blepharoplasty approaches.

When discussing medical history, the surgeon should ask about thyroid eye disease, poorly controlled hypertension, anticoagulant use, blepharitis, facial nerve dysfunction, history of keloid scars or herpes zoster ophthalmicus, and visual field problems (5). Particular attention should be paid to a history of dry eye symptoms or regular use of lubricating drops. The surgeon should inquire about dry eye symptoms in several ways, as some patients may only report "allergic"-type symptoms or watering without emotional stimulation (Fig. 187.14). All patients, and particularly those with symptoms, should be informed that blepharoplasty can cause or exacerbate dry eye symptoms. The surgeon should be aware that a subclinical dry eye condition can worsen to a keratoconjunctivitis sicca with the mechanical alteration that occurs following cosmetic eyelid surgery (6).

A thorough physical examination is critical to selecting the correct procedure and avoiding postoperative complications. The surgeon should look for the following: orbital fat pseudoherniation, orbicularis hypertrophy, dermatochalasis, tear trough deformity, lid laxity, scleral show, negative vector, festooning, malar bags, midface ptosis, and fine rhytids.

Orbital fat pseudoherniation and dermatochalasis are the most common reasons patients seek lower eyelid blepharoplasty. In most cases, fat pseudoherniation is obvious on inspection. This finding can be confirmed by gentle pressure on the globe and examining the patient in upward gaze. Orbicularis hypertrophy can be differentiated from fat pseudoherniation by having the patient smile or squint. While fat pseudoherniation can be treated with either a transconjunctival or transcutaneous approach, skin or muscle excess can only be treated with an incision through the anterior lamella.

The contour of the lower lid should be closely examined. The surgeon should assess for a "tear trough deformity." If a surface depression is noted along the inferomedial aspect of the orbital rim, a fat transposition to efface the "tear trough" should be performed (see procedure section).

Figure 187.13 **A**: Excellent candidate for blepharoplasty. This patient has obvious pseudoherniation of orbital fat, tear trough deformity, and some excess skin and muscle. **B**: Poor candidate for blepharoplasty. This patient has hyperpigmentation and fine rhytids of the lower eyelid.

Examination for lid laxity deserves special attention. Failure to note this common sign is a missed opportunity for the surgeon and can result in patient dissatisfaction and an increased risk of postoperative complications. Lower eyelid laxity is evaluated by two common clinical tests: the snap test and distraction test. The snap test assesses canthal stability and orbicularis and tarsal strength (7). The test is performed by gently pulling the lower lid toward the orbital rim and releasing. Obvious scleral show or slow return to the resting position (greater than 1 second) indicates poor lid support. The distraction test is performed by grasping the lower lid and pulling it away from the globe. Distraction of the eyelid greater than 10 mm indicates poor lid support. If the distraction or snap tests are positive, failure to adequately support the lid can lead to ectropion, epiphora, or exposure keratitis (7) (Fig. 187.15A and B).

The position of globe relative to the eyelid and maxilla should also be examined. Assessing for scleral show and negative vector can change the surgical plan and prevent postoperative lid malposition. In a normal-vector orbit, the cornea rests in a vertical plane with the inferior orbital rim. When a negative vector is present, the cornea lies in plane anterior to the inferior orbital rim. In patients with negative vector orbits, transcutaneous approaches with shortening of the anterior lamella can result in significant postoperative lid malposition. If scleral show or negative vector is noted preoperatively, the surgeon can plan procedures to support the lower lid, such as intraoperative canthopexy (see below) or postoperative lid taping. Patients with negative vector orbits should also have conservative fat removal, as they are more prone to developing a "hollowed" appearance.

Festooning and malar bags are signs commonly seen with aging and indicate orbicularis laxity. They can only be corrected with an extended transcutaneous approach to blepharoplasty with undermining in the suborbicularis plane inferior to the orbital rim. The surgeon should also inspect the lid for horizontal excess, as lid shortening procedures may also be indicated.

Malar edema, midface ptosis, and fine rhytids are not correctable with blepharoplasty. Once noted, the surgeon should educate the patient and discuss adjunctive procedures, such as a midface lift or resurfacing. The surgeon should also discuss the persistent and recurring nature of malar edema, as it may not be corrected with *any* surgical procedure.

PHOTOGRAPHY AND CONSENTS

Although often underestimated as a formality, photography and consents are among the most important aspects of any cosmetic procedure.

Standardized photography for eyelid surgery includes full face and close-up views. Close-up views should extend from just above the eyebrows to the level of the nasal ala. The following close-up views should be obtained: frontal, frontal in upward gaze, frontal with eyes closed, bilateral oblique, and bilateral profile. Full face frontal and bilateral oblique views are also obtained (8) (Fig. 187.16).

A lower eyelid blepharoplasty consent form should include a complete discussion of goals, limitations, alternatives, expected outcomes, risks, and potential for additional surgery. The consent should explicitly state that blepharoplasty will not remove crow feet, malar bags, fine wrinkles, or dark circles. Expected outcomes should include swelling, asymmetric bruising, temporary tearing, need for artificial tears because of dry eye, itching, blurry vision, tightness on eyelid closure, fine scarring of the lower eyelid, slight scleral show, and possible minor asymmetries in eyelid position. Risks outlined should include asymmetry, bleeding, infection, blurriness, double vision, chemosis, ectropion, visual loss, lower lid sagging, rounding of the corner of the eye, and chronic dry eye syndrome.

Figure 187.14 Typical "dry eye questionnaire." Blepharoplasty surgeons should always inquire about dry eye symptoms prior to embarking on surgery.

Figure 187.15 **A**: Snap test. The examiner pulls the lower lid toward the orbital rim and releases. Obvious scleral show or slow return to the resting position (greater than 1 second) indicates poor lid support. **B**: Distraction test. The examiner grasps the lower lid and pulls it away from the globe. Distraction of the eyelid greater than 10 mm indicates poor lid support.

Figure 187.16 Standard views for blepharoplasty photos.

SURGICAL PROCEDURE

The main approaches for lower lid blepharoplasty are transconjunctival and transcutaneous. Both have clear indications and should be part of a surgeon's armamentarium. Once the surgeon has decided on an approach, adjunctive procedures should be considered including canthopexy or canthoplasty and lower lid resurfacing (chemical or laser).

TRANSCONJUNCTIVAL APPROACH

The transconjunctival approach is ideally indicated for younger patients (15 to 35 years old) without anterior lamellar pathology. Otherwise stated, these patients have hereditary pseudoherniation of orbital fat without true excess skin or muscle (Fig. 187.17). Relative indications include patients who do not want an external scar or those with a history of abnormal scarring. The transconjunctival approach can be safely combined with resurfacing procedures or "pinch" skin removal in those with fine rhytids or minimal excess skin of the lower eyelid, respectively (9).

Two transconjunctival approaches are routinely performed: preseptal and postseptal. The preseptal approach involves dissecting inferiorly along the avascular plane between the orbital septum and orbicularis oculi muscle (Fig. 187.18). The postseptal approach is a more direct approach to the orbital fat through the conjunctiva and the lower lid retractors closer to the conjunctival fornix (Fig. 187.19). While the preseptal approach takes slightly longer to perform, it is generally considered to provide better visualization of the individual fat pads and poses less risk to the integrity of the inferior oblique muscle. The

Figure 187.17 Before and after transconjunctival blepharoplasty. Ideal candidates for this approach have pseudoherniation of orbital fat without skin or muscle excess.

preseptal approach also allows the surgeon to approach the individual fat compartments from the same anterior direction as typically seen from the transcutaneous skin–muscle flap approach.

PRESEPTAL TRANSCONJUNCTIVAL TECHNIQUE

Once an appropriate level of sedation is achieved, topical 2% tetracaine is instilled into the inferior fornix of each eye. Local anesthetic (lidocaine with epinephrine) is then injected into the subconjunctival plane of the lower eyelid.

After adequate anesthesia is obtained, a sharp double hook (followed by a Desmarres retractor or double ball hook) is used to retract the lid inferiorly. Light bipolar cautery can be used prior to incision to conservatively cauterize the planned incision site along the central portion of the conjunctiva. An incision is made through the conjunctiva 2 mm inferior to the tarsus. The conjunctiva is then opened laterally and medially; the inferior lid retractors are transected sharply with a small curved scissors. The conjunctiva and inferior retractor muscles are then reflected superiorly over the cornea with a 5-0 silk suture, thus providing corneal protection and countertraction (alternatively, corneal protectors can also be used) (Fig. 187.20A and B).

The orbicularis oculi muscle is then separated from the orbital septum inferiorly to the orbital rim. The surgeon should then closely examine the preoperative pictures and intraoperative findings to determine where to incise the septum and approach the orbital fat pads. Westcott scissors are used to make the incision through the orbital septum. The pseudoherniated fat is very carefully teased out. If fat is not being transposed, it is lightly grasped, cauterized, and excised (Fig. 187.20C). If fat transposition is being performed, a precise pocket is elevated in the suborbicularis plane corresponding to the region of soft tissue depression. The medial fat pad is redraped over the orbital rim and sewn into place using a 6-0 absorbable suture in an interrupted fashion.

After completion of fat resection and/or transposition, the lower eyelid skin is redraped in its anatomic position

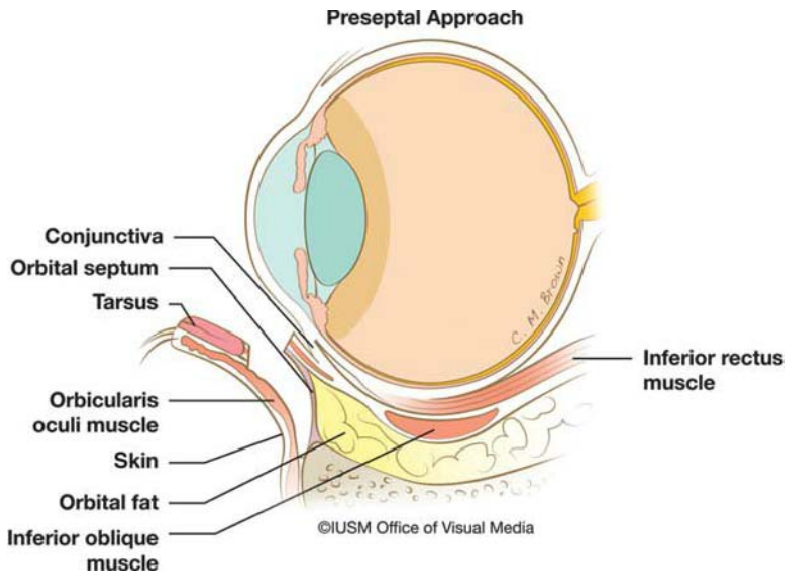

Figure 187.18 Preseptal transconjunctival approach.

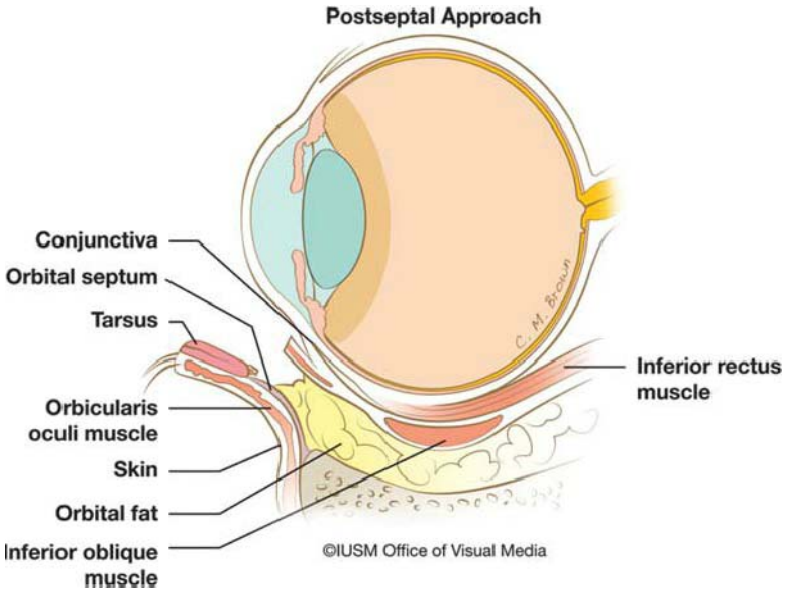

Figure 187.19 Postseptal transconjunctival approach.

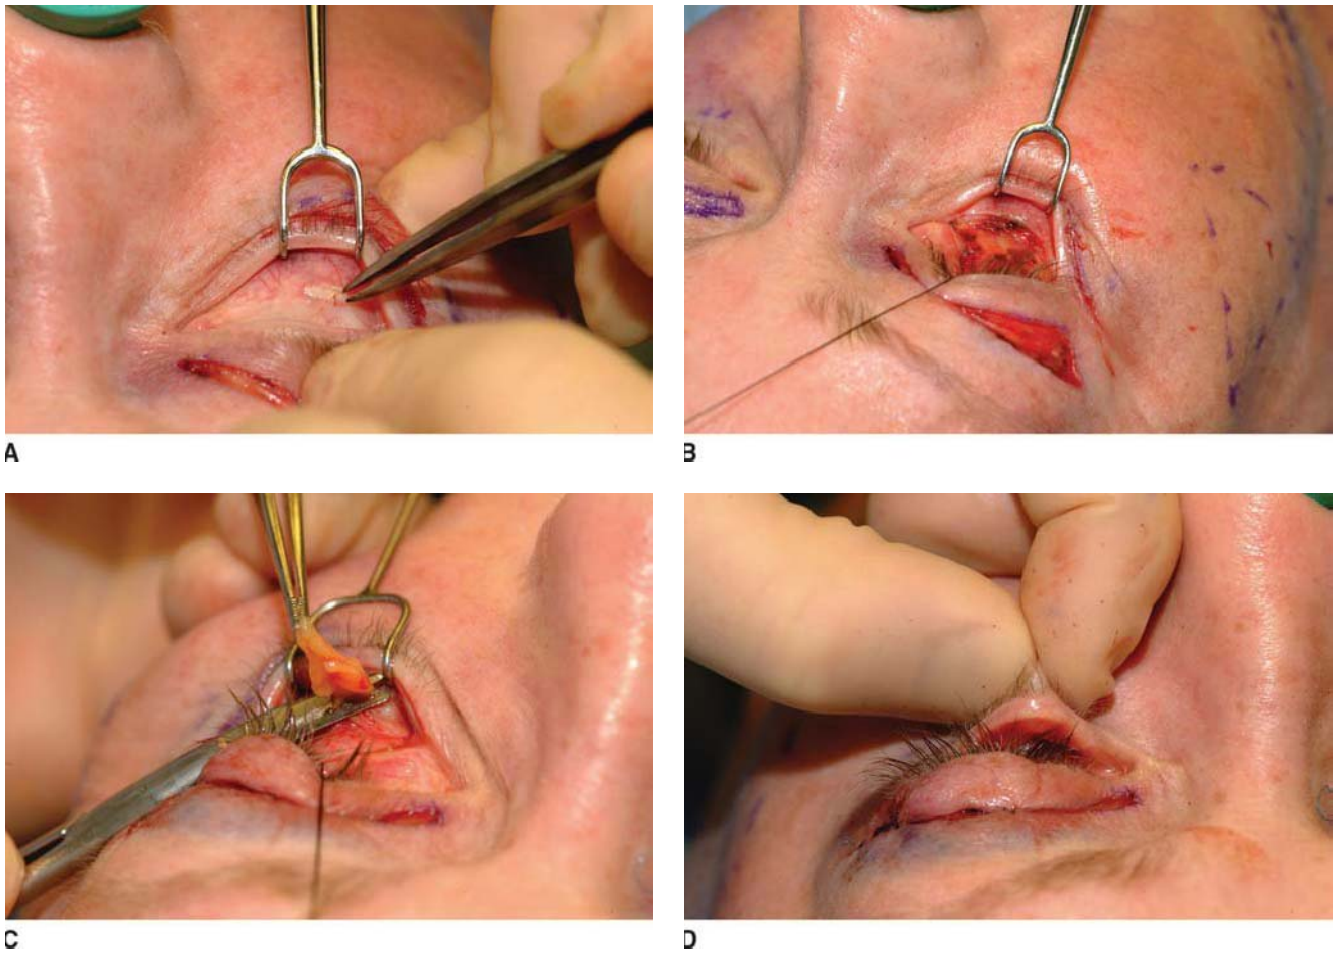

Figure 187.20 Preseptal transconjunctival approach. **A**: Light bipolar cautery is used to conservatively cauterize the planned incision site. **B**: Retraction of the conjunctival flap (comprised of conjunctiva, lower lid retractors, and orbital septum) provides countertraction and corneal protection. **C**: Pseudoherniated fat is gently grasped, cauterized, and excised. **D**: Upon completion of fat resection, the skin is picked up and snapped into place at the inferior limbus. Sutures are not necessary.

A B

Figure 187.21 Before and after photos following skin–muscle flap blepharoplasty. **A**: Preoperative. **B**: Postoperative. Note barely perceptible scar.

and evaluated for any residual bulging or irregularity. After acceptable contour is ensured, the silk suture is removed and the skin flap is picked up, raised, and snapped into position over the lower limbus. Sutures are not necessary in this technique (Fig. 187.20D).

If a skin pinch is planned, forceps are used to grasp 2 to 3 mm of redundant skin just inferior to the lash line. Scissors are used to sharply excise the skin. The edges are reapproximated with 6-0 fast absorbing gut sutures or tissue glue (8).

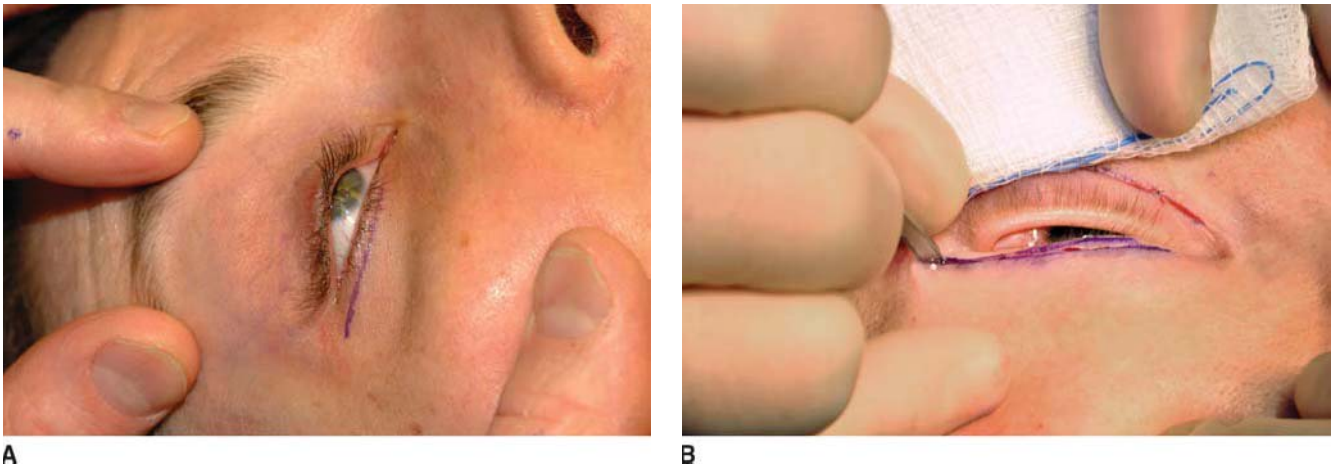
TRANSCUTANEOUS SKIN–MUSCLE FLAP APPROACH

The transcutaneous approach is indicated for patients with anterior lamellar pathology. This is usually an older age group of patients with excess lower eyelid skin, muscle, or both. Some surgeons have avoided this technique due to an increased risk of postoperative lid position abnormalities. However, if performed correctly, it can yield excellent, consistent results with a barely perceptible scar (10) (Fig. 187.21).

SKIN–MUSCLE FLAP TECHNIQUE

Once an appropriate level of anesthesia is achieved, the lower eyelids are infiltrated transcutaneously with local anesthetic (lidocaine with epinephrine) deep to the orbicularis oculi muscle.

The skin incision is performed with a 15 Bard Parker blade 2 mm inferior to the lower lid margin. The incision extends from just lateral to the lower punctum to a position 6 mm lateral to the lateral canthus (Fig. 187.22A and B). Fine curved scissors are then used to dissect through the orbicularis muscle at the lateral aspect of the incision. Blunt scissors are positioned posterior to the muscle at the lateral aspect of the incision, and with spreading motions of the scissors, the skin–muscle flap is elevated off the orbital septum. Dissection proceeds from the inferior orbital rim inferiorly to the incision superiorly (Fig. 187.23). The subciliary incision is then completed using the scissors in a beveled manner to ensure preservation of the pretarsal portion of the orbicularis oculi muscle, thus minimizing the risk of postoperative lower eyelid malposition (Fig. 187.24).



A B

Figure 187.22 Skin–muscle flap blepharoplasty. **A**: Preoperative marking. **B**: Incision.

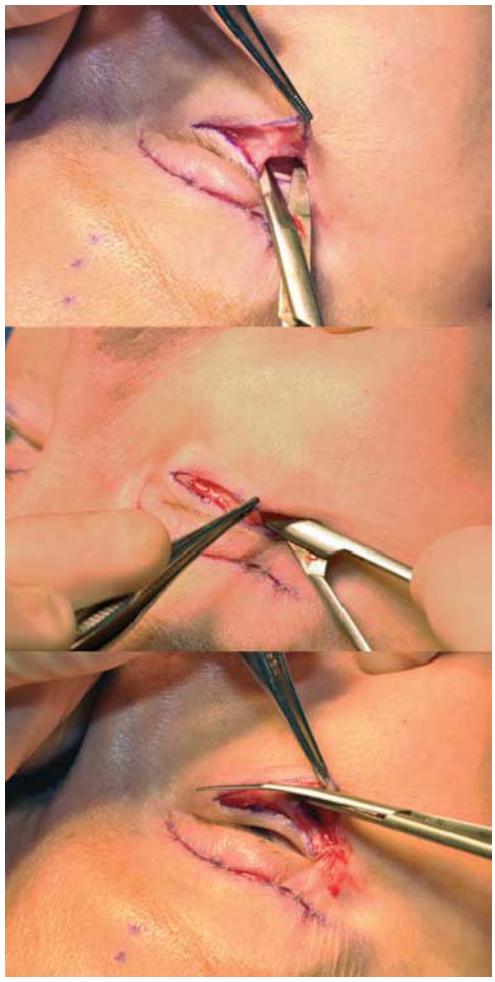


Figure 187.23 Elevation of skin muscle flap during blepharoplasty.

Access to the orbital fat compartments is obtained through small, selected openings of the orbital septum. Gentle palpation of the globe results in herniation of orbital fat through the aforementioned openings of the orbital septum. Bipolar cautery is then used to cauterize the fat pad prior to excision.

This procedure is performed for the lateral, middle, and medial fat compartments, as deemed appropriate. A conservative approach to fat resection is maintained to avoid the creation of a "sunken" or "hollowed" appearance (Fig. 187.25A).

If fat transposition is being performed, dissection inferior to the infraorbital rim is performed and a pocket is created in a supraperiosteal plane in the location of the nasojugal groove. A small opening is made in the orbital septum to gain access to the medial fat pocket. Once the medial fat is isolated, it is transposed over the orbital rim in the suborbicularis plane to efface the corresponding soft tissue depression. The transposed orbital fat is then secured to the periosteum using interrupted 6-0 absorbable suture (Fig. 187.25B).

On completion of fat resection and/or fat transposition, the skin–muscle flap is repositioned. In an anesthetized patient, single-finger pressure is applied at the inferomedial portion of the melolabial mound to create a maximal stretch effect. If the patient is awake, he or she is asked to open his or her mouth and look up. Following this, an inferiorly directed segmental cut is made at the lateral canthus to determine the amount of excess skin to excise. A tacking suture is placed to maintain the position of the skin–muscle flap; overlapping skin is trimmed. A 1- to 2-mm strip of muscle is resected to prevent overlapping of muscle and ridge formation with closure of the subciliary incision. A conservative amount of skin and muscle is resected. The orbicularis oculi muscle is then suspended to the periosteum of the lateral orbital rim with 5-0 poliglecaprone (Monocryl) suture. The deep tissues are then reapproximated at the lateral aspect of the incision using 6-0 absorbable suture (Fig. 187.26A–C).

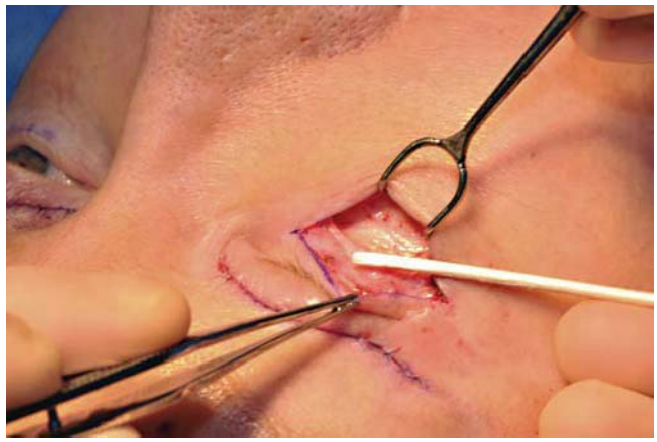

Figure 187.24 Preservation of the pretarsal orbicularis oculi muscle during skin–muscle flap blepharoplasty.

Following muscle suspension, the subciliary incision is closed with 7-0 blue polypropylene suture at the lateral canthus in a simple interrupted fashion. The remainder of the incision is closed with 6-0 fast absorbing plain gut suture in a running fashion (Fig. 187.26D).

SKIN FLAP TECHNIQUE

The technique of lower lid blepharoplasty using a subciliary incision and "skin-only" flap is rarely used and of historical interest only.

ADJUNCTIVE PROCEDURES

Canthopexy and Canthoplasty

All surgeons performing blepharoplasty should be well versed in procedures to support the lower eyelid. In patients who have weak or lax lower eyelids, the contractile healing forces following blepharoplasty are unopposed, which can lead to retraction and ectropion. To prevent such complications, a canthoplasty or canthopexy should be performed at the time of surgery.

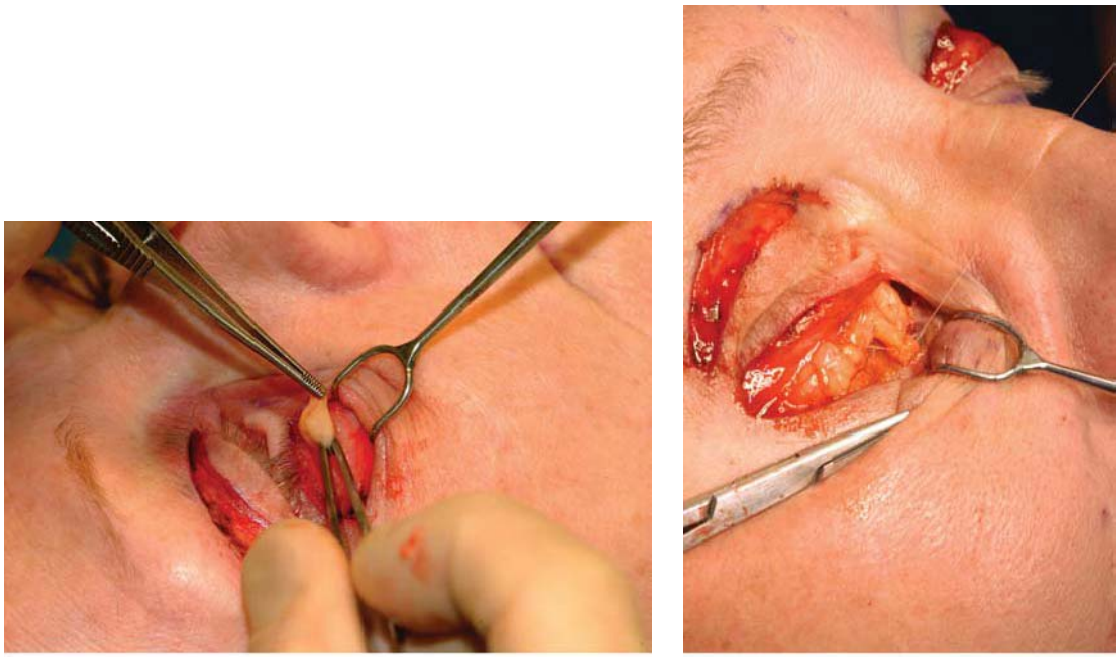

Figure 187.25 Skin–muscle flap blepharoplasty. **A**: Fat resection. **B**: Fat transposition.

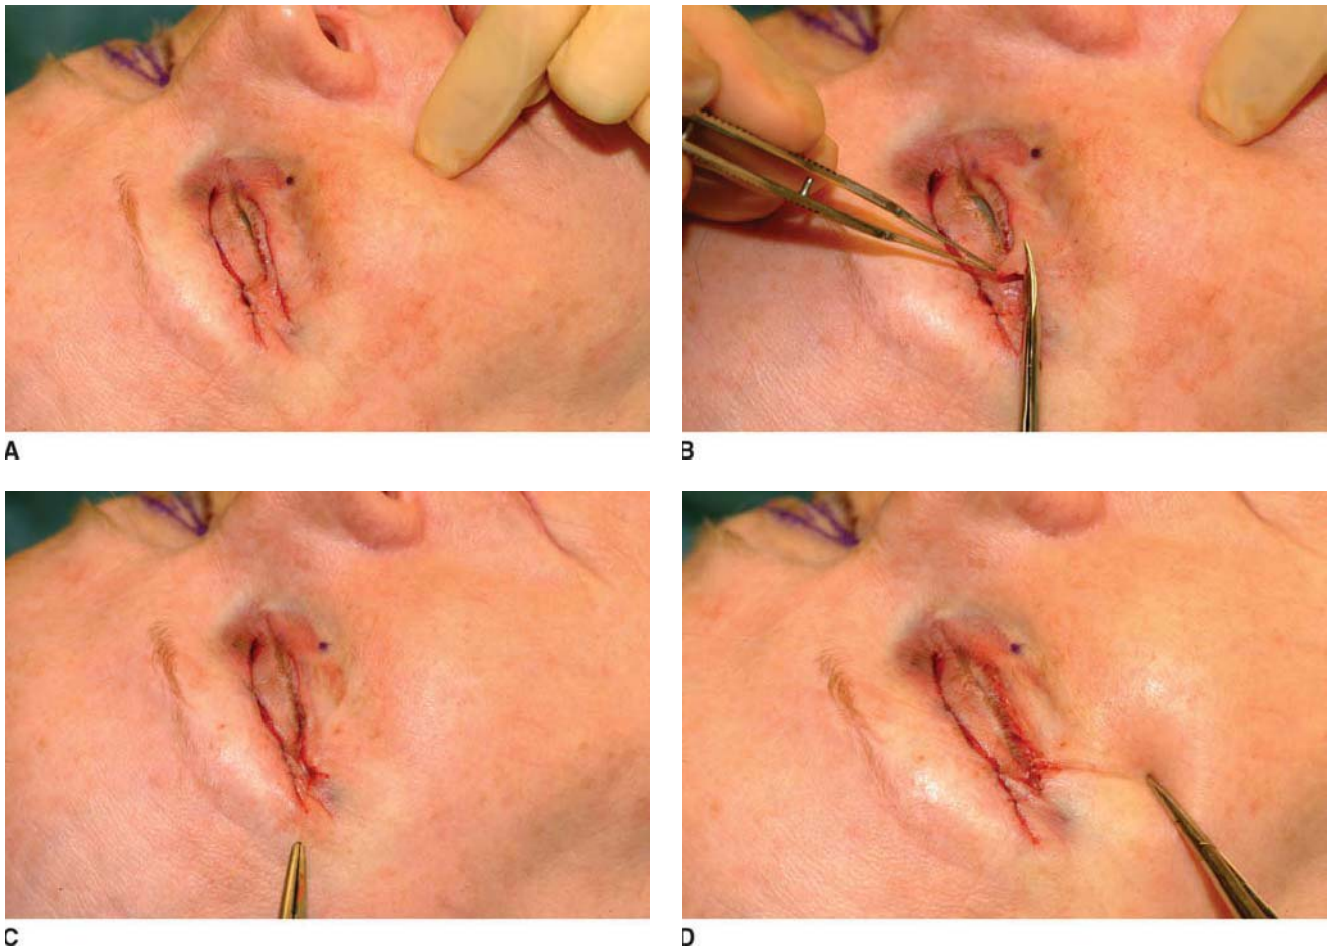

Figure 187.26 Closure of skin–muscle flap approach. **A**: Single finger pressure at the melolabial mound. **B**: Trimming of the skin flap. **C**: Orbicularis suspension suture. **D**: Closure of the external incision.

In cases where temporary support is needed, canthopexy is accomplished before closure of the upper and lower eyelid incisions. A suspension suture of 5-0 poliglecaprone (Monocryl) is placed between the periosteum of the inner aspect of the superolateral orbital rim and the lower lid tarsus, lateral canthal tendon, and pretarsal orbicularis. The suture is tunneled under the bridge of skin between the upper and lower eyelid incisions. If an upper eyelid blepharoplasty is not performed at the time of canthopexy, a separate stab incision can be made at the superolateral orbital rim (Fig. 187.27A–D).

A canthoplasty is performed in cases of significant lid laxity, when horizontal shortening is indicated, or if a more permanent solution is desired. Eyelid scissors are used to perform a lateral canthotomy and inferior canthol-ysis. Next, the lateral tarsal strip is created by excising conjunctiva from the posterior aspect of the tarsus and excising skin and muscle from the anterior aspect of the tarsus. The tarsal strip is then sutured to the periosteum of the medial aspect of the lateral orbital rim in a posterosuperior position with a 5-0 clear polypropylene suture. The orbicularis is then suspended to the periosteum of the lateral orbital rim at the tubercle with 5-0 poliglecaprone. The lower eyelid incision is then closed in the standard fashion (Fig. 187.28A–D).

LOWER EYELID RESURFACING

Standard blepharoplasty techniques do not treat fine, "crepy" periocular rhytids. While a transcutaneous blepharoplasty can address excess skin, overtightening the skin–muscle flap during surgery to efface fine rhytids can lead to disastrous complications, including rounding, scleral show, or frank ectropion. To safely address crepiness, a resurfacing procedure can be performed at the time of blepharoplasty (Fig. 187.29A and B).

While a complete discussion of lower eyelid resurfacing is beyond the scope of this chapter, it is sufficient to say that resurfacing procedures are characterized as superficial, medium, or deep. Selection of the depth of treatment is based upon degree of preoperative

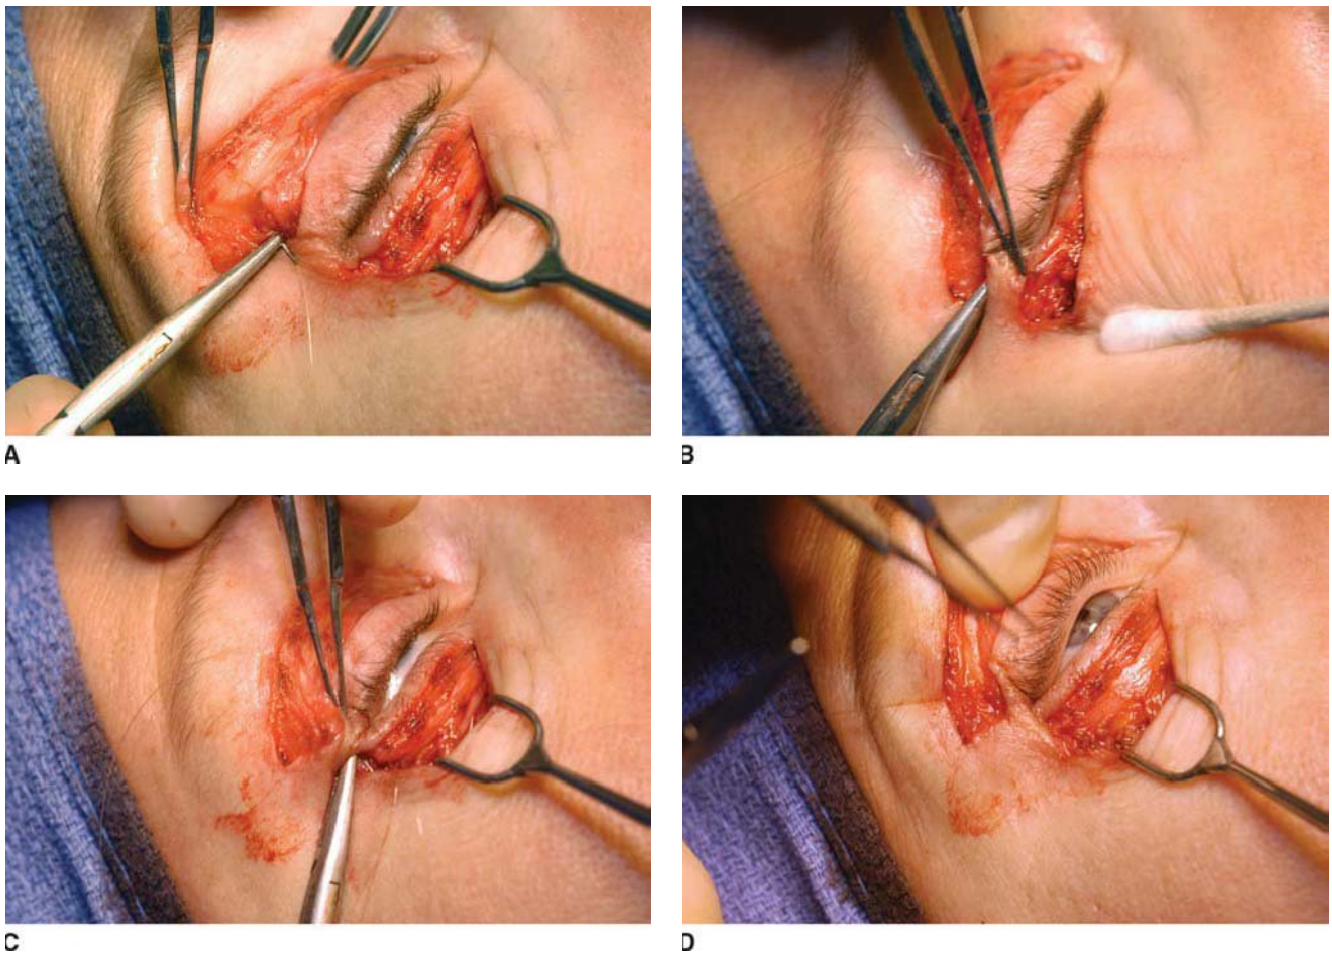

Figure 187.27 Canthopexy. **A**: Suture placed through periosteum of superolateral orbital rim. **B**: Suture placed through the pretarsal orbicularis and tarsus. **C**: Suture tunneled between upper and lower eyelid incisions. **D**: Cinching of suture. dermatochalasis, photoaging, and hyperpigmentation. A superficial depth of resurfacing can be achieved with superficial laser treatments. Medium depth modalities include trichloroacetic acid 35% pretreated with Jessner's solution (composed of 14 g resorcinol, 14 g salicylic acid, and 14 mL lactic acid mixed in ethanol) and phenol 88% USP. A deep depth of resurfacing can be achieved with a CO_2 laser or Baker's peel.

Figure 187.29 Before and after photos following skin–muscle flap blepharoplasty with lower eyelid chemical peel (phenol 88% USP). **A**: Preoperative. **B**: Postoperative.

FILLERS IN THE LOWER EYELID

Hyaluronic acid fillers can be successfully used as a temporary treatment for the "tear trough" deformity. Selection of filling agent is critical, as overly hydrophilic compounds can lead to an unattractive "puffy" appearance. For this reason, the authors exclusively use Restylane (Medicis Aesthetics Inc., Scottsdale, AZ) in the delicate lower eyelid region. The tear trough region is commonly treated with small incremental aliquots of filler in the supraperiosteal suborbicularis plane with massage following injection to smooth out irregularities (Fig. 187.30A and B).

MIDFACE LIFT

In patients who present with midface ptosis or a double convexity deformity, a midface lift is a useful adjunctive procedure to extended skin–muscle flap blepharoplasty. While a discussion of midface lift is beyond the scope of this chapter, it is important to note that it does increase recovery time and should only be performed in carefully selected patients (Fig. 187.31A and B).

FAT GRAFTING

Fat grafting has been discussed for decades in the lower eyelid region. It is the senior author's opinion that fat grafting in this region is fraught with complications, such as visible lumps and unevenness, and is not commonly employed as an adjunctive procedure in his practice.

COMPLICATIONS

All blepharoplasty surgeons should expect to encounter and treat complications. Fortunately, sight-threatening complications, such as retroorbital hematoma, are

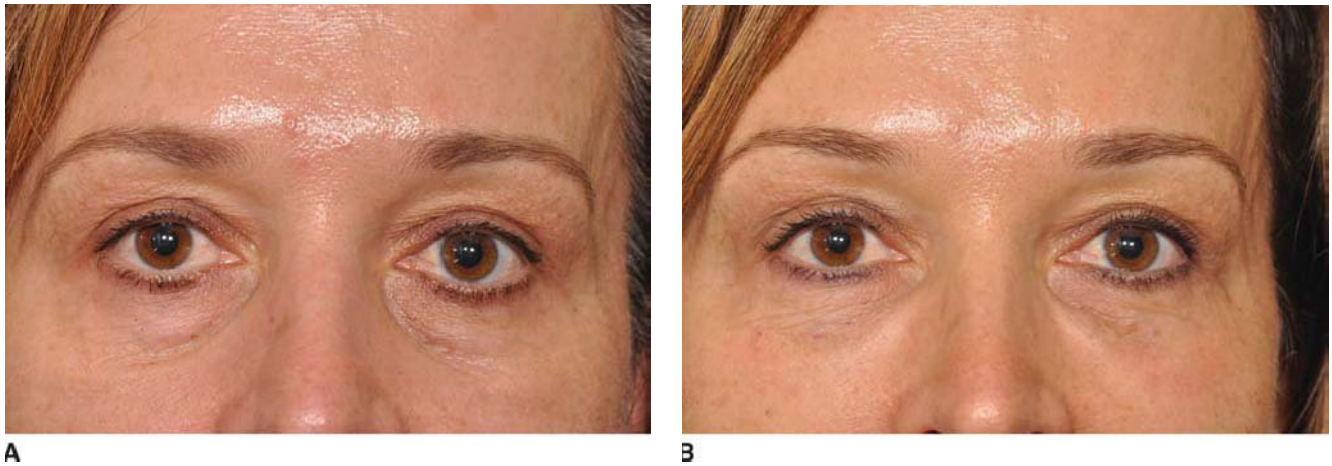

Figure 187.30 Before and after photos of Restylane filler in the lower eyelid "tear trough" region. **A:** Prefiller. **B:** Postfiller.

Figure 187.31 Pre and postoperative photos of mid-facelift result with lower lid blepharoplasty. **A:** Preoperative. **B:** Postoperative.

extremely rare. The best outcomes are usually achieved with prompt recognition and early treatment.

DRY EYE SYMPTOMS, BLURRY VISION, AND CHEMOSIS

Dry eye symptoms, blurry vision, and chemosis are part of a common spectrum of expected sequelae or complications caused by the mechanical disruption of eyelid function and/or lagophthalmos following surgery.

Prophylaxis for of dry eye symptoms is important following eyelid surgery. All blepharoplasty patients should be placed on an aggressive lubrication regimen consisting of ophthalmic drops and ointment; they should be encouraged to "over-lubricate" in the first 10 days following surgery. Patients should also be told during the preoperative consult that blepharoplasty can lead to "visual downtime," which can last 2 weeks. They should expect to modify their lifestyles (i.e., no driving, contact lenses, or prolonged computer use) during the first several days after surgery. Unfortunately, dry eye symptoms can become chronic, requiring indefinite use of lubrication or adjunctive procedures.

Chemosis is characterized by yellowish conjunctival edema that typically occurs in the first 7 days following blepharoplasty (Fig. 187.32). Large studies have found the incidence to range from less than 1% to 12% (11) of patients following blepharoplasty (12,13). Although the exact cause of chemosis is unknown, disruption of the lower eyelid lymphatics (particularly in the region of the lateral canthus) and conjunctival exposure from lagophthalmos are thought to be contributing factors. Conservative treatment consists of aggressive lubrication, supportive lid taping, nighttime eye patching, and limiting sodium consumption. Topical steroid drops and rarely surgical procedures, such as drainage conjunctivotomy or temporary tarsorrhaphy, are also occasionally indicated. Most cases resolve within 6 weeks.

LID POSITION ABNORMALITIES

Lid malposition, which includes rounding, retraction, and ectropion, is considered by some to be the most common complication following the transcutaneous approach to blepharoplasty (13) (Fig. 187.33). It has also been

Figure 187.32 Chemosis following skin muscle flap blepharoplasty.

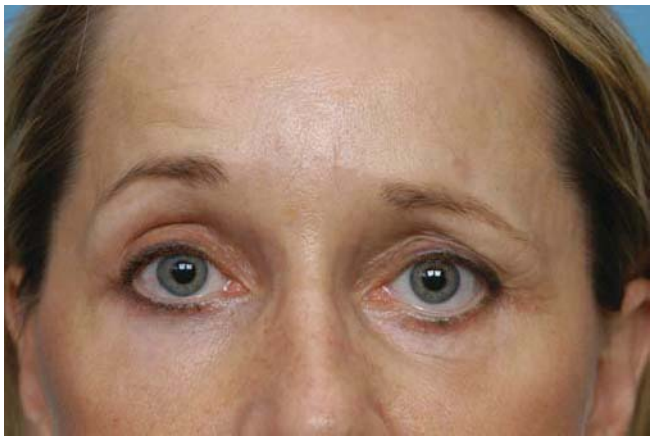

Figure 187.33 Lid malposition following blepharoplasty.

Figure 187.34 Preseptal hematoma immediately following blepharoplasty.

documented following the transconjunctival approach (9). The risk of symptomatic malposition is greater in patients with preexisting lid laxity, leading some to advocate routine canthal support in the form of canthopexy or canthoplasty during blepharoplasty (13).

If mild retraction is noted postoperatively, ocular lubrication, upward massage, and lid taping are recommended. Steroid injections can also be performed to oppose the forces of contracture, particularly if a scar band is palpated. When symptomatic retraction or ectropion develop, surgical management is usually indicated. In cases of horizontal lid excess, a canthoplasty is performed. When scarring of the anterior or posterior lamella is noted, spacer grafts are usually employed.

MILIA

Epithelial remnants can become trapped within the incision, manifesting as small white nodules, or milia. Treatment consists of incision and extraction or marsupialization. This can easily be performed with an 18-gauge needle in the office.

ALLERGIC CONJUNCTIVITIS

Toxoallergic blepharoconjunctivitis can be caused by a variety of topical treatments (prescribed and over the counter) used in the postoperative period. Common causes include preparations containing neomycin or preservatives. Patients will report redness, itching, or increasing swelling and inflammation. Cessation of the offending agent is curative, although topical steroids, cool compresses, and diphenhydramine can be used for symptom relief (5).

INFECTION

The rich vascularity of the eyelids has a protective effect against infection following blepharoplasty. Although extremely rare, infections have been reported, including methicillin-resistant *Staphylococcus aureus*, mycobacterial, and even necrotizing fasciitis. Clinical suspicion, cultures, and appropriate antibiotics are essential for treatment.

PRESEPTAL HEMATOMA

Although rare, preseptal hematoma can be seen following blepharoplasty (Fig. 187.34). This complication can often be prevented with meticulous intraoperative hemostasis. Treatment consists of opening of incisions, decompression, and cautery of any offending vessels.

RETROORBITAL HEMATOMA

Retroorbital hematoma is considered to be the most feared complication following blepharoplasty. The incidence of orbital hemorrhage has been found to range between 1:2,000 (0.05%) and 1:20,000 (0.005%). The incidence of vision loss due to hematoma has been found to range from 1:10,000 (0.01%) to 1:30,000 (0.003%) (5,14).

Symptoms of retroorbital hematoma usually present within the first 24 hours after surgery. The most commonly reported risk factor is hypertension (14). Patients will complain of pain and pressure. Signs include increased intraocular pressure, eyelid ecchymosis, and a tense orbit. Treatment should consist of immediate decompression by opening all incisions with exploration to identify and cauterize any offending vessel. Medical therapy consists of oxygen, topical beta-blockers, intravenous steroids, mannitol, and acetazolamide. If the wound cannot be adequately explored and decompressed through existing incisions, surgical management consists of lateral canthotomy with inferior cantholysis.

CONCLUSIONS

Lower eyelid blepharoplasty is a detail-oriented procedure. It requires diligence in preoperative planning, intraoperative technique, and postoperative management. Preparation and thoroughness are the keys to success in this rewarding operation.

ACKNOWLEDGMENT

The authors would like to acknowledge Nancy Rothrock for her medical photography and Christopher M. Brown at the Indiana University School of Medicine for his medical illustrations in this chapter.

HIGHLIGHTS

- Thorough knowledge of lower eyelid anatomy is required prior to embarking on blepharoplasty.
- Lower lid blepharoplasty can correct orbital fat pseudoherniation, excess skin and muscle, mild festooning, and tear trough deformities. Blepharoplasty does *not* correct abnormal skin pigmentation, fine rhytids, or large malar bags/edema.
- Physical examination prior to blepharoplasty should always include testing for lower eyelid laxity. Performing blepharoplasty in patients with lid laxity requires lid-supporting adjunctive procedures (canthopexy or canthoplasty). Failure to do this can lead to rounding, scleral show, and frank ectropion.
- The preoperative physical examination should guide the surgeon in selecting the correct approach for blepharoplasty. The transconjunctival and transcutaneous approach each has specific indications.
- Prompt recognition and treatment of complications are essential in avoiding long-term sequelae following blepharoplasty.

Rhytidectomy (Face-Lift)

188

Russell W. H. Kridel *Zahi Abou Chacra*

The principal role of rhytidectomy is to elevate facial tissues that have descended with the aging process. Although skin excision is performed in a face-lifting procedure, contrary to the once predominant common belief, it is often not the dominant or sole goal one should try to achieve. Most current face-lift techniques rely on resuspension of the superficial musculoaponeurotic system (SMAS), whether through a SMAS or deep plane approach, with redraping and removal of skin without tension. The authors are witness to a steady evolution of technical and anatomical advances producing a new generation of face-lifts. Presently, the authors continue to evaluate these newer techniques in search of the ideal procedure, which will give our patients a long-term, natural correction with rapid recovery and few complications.

GENERAL CONSIDERATIONS AND ADJUNCTIVE PROCEDURES

Aging face patients requesting consultation for a face-lift generally seek a youthful, more rested appearance. These patients have a well-developed self-image and do not want to look different. Rather they desire a natural-appearing result that turns back the hands of time to a more youthful version of themselves. For the surgeon, the goal is to determine what physical characteristics of the face are contributing to the impression of aging, which stigmata are reversible, and by what means. Ideally, the surgeon brings to this consultation a thorough understanding of the processes that lead to an aged appearance and is familiar with a wide variety of medical and surgical interventions appropriate for addressing the clinical problem. As with all elective facial plastic surgery, it is imperative for the surgeon to achieve a balanced, harmonious result. The patient who presents with an interest in face-lift who also has brow ptosis and four-quadrant dermatochalasis can be poorly served if the incongruity is not discussed prior to proceeding with the surgery. Moreover, oftentimes these patients will be left with more stigmata of a lifted appearance should they only address the lower face due to this incongruity. For these reasons, in addition to the face-lift, it is important to discuss the potential benefits of browlift, blepharoplasty, skin resurfacing (laser, chemical peel, and dermabrasion), as well as adjunctive procedures such as soft tissue fillers (like hyaluronic acid and calcium hydroxyapatite), fat injection, alloplastic implants, or muscle-paralyzing agent injections like Botox and newly approved Dysport. These are adjunctive procedures that complement face-lifting surgery and address the general theme of facial rejuvenation, which sometimes face-lifting cannot achieve alone.

A recent paradigm shift among many authors is volume preservation and restoration in the aging face, rather than just resuspension of deep tissues. This paradigm shift is partly demonstrated by the increasing use of biologic and synthetic injectable fillers in facial plastic surgery. Other commonly used volume-augmenting strategies for facial rejuvenation include fat injections and alloplastic implants. Proponents of such techniques argue that fat and tissue atrophy happen along with gravitational changes. Recently, Lambros (1) compared pictures taken up to 50 years apart and studied the effect of aging on the midface and periorbital complex. He concluded that there was little ptosis at the lid–cheek junction and that the aged appearance was partly due to volume loss. In another of his papers, he proposed how the addition of volume may give better results than traditional surgical methods (2). He emphasized that a face that has enough tissue volume is the best predictor of a face-lift outcome. It is our opinion and the one of many other surgeons that volume restoration is an important adjunct but does not replace the need for a surgical lift. The authors do, however, recognize that for some patients with volume loss as well as tissue descent, both problems must be addressed to produce natural, harmonious, and complimentary results.

The term face-lifting is sometimes a misleading term to patients, as it does not spell out which structures will be lifted. It says nothing about the neck, which is a main area of most lifting procedures, and on the other hand, it implies that the upper third of the face will be lifted, which most surgeons consider another procedure that they would address separately, such as with a forehead lift.

Most patients undergoing today's typical face-lift are really getting a lower face- and neck lift. To lift the upper third of the face, for instance, one should rely on a forehead lift. In his recent publication, McCollough stresses that the term face-lift is often inadequately used. He describes five progressive stages of aging and proposes a classification that helps matching the specific aging stage with the appropriate rejuvenation treatment (3). His system describes procedures based on anatomic locations such as temple lift, forehead lift, cheek lift, and neck lift, diminishing confusion around the more generic widely used face-lift term. This chapter focuses only on the anatomy and clinical considerations of the present-day rhytidectomy procedure.

PHYSIOLOGY OF THE AGING FACE

To understand the present-day rhytidectomy procedure, the surgeon must have full knowledge not only of the underlying surgical anatomy but also of the aging physiology of the face, which leads patients to seek rejuvenation surgery. In general, the aging face presents five landmarks that are points of interest to patients and surgeons alike. These areas include (a) the jowl, (b) the deepened nasolabial folds and lateral perioral jowling, (c) the platysma banding and submental fullness in the neck region, (d) the orbicularis oculi and malar fat pad ptosis, and (e) the aging skin itself (Fig. 188.1A).

In youth, the facial skin is maintained in normal anatomic position by retaining "ligaments" that run from deep facial structures to the dermis itself (4). With aging, attenuation of these "ligamentous" supports then results in malar soft tissue descent. The result of this descent is not only deepening of the melolabial folds but also jowling of the platysma and soft tissue between the masseteric and mandibular ligaments at the jawline. Moreover, this descent of the malar fat pad along with ptosis of the orbicularis oculi also results in hollowing in the infraorbital region. Finally, loss of platysma muscle tone results in anterior banding and the classically pictured "turkey gobbler" neck (5) (Fig. 188.1B).

Separate from the described underlying soft tissue changes, the surgeon must note the cumulative effects of the inherent aging process coupled with the effects of environmental exposure on the skin itself. While a comprehensive review of the changes associated with aging skin is beyond the scope of this chapter, it is important for the surgeon to have a fundamental understanding of

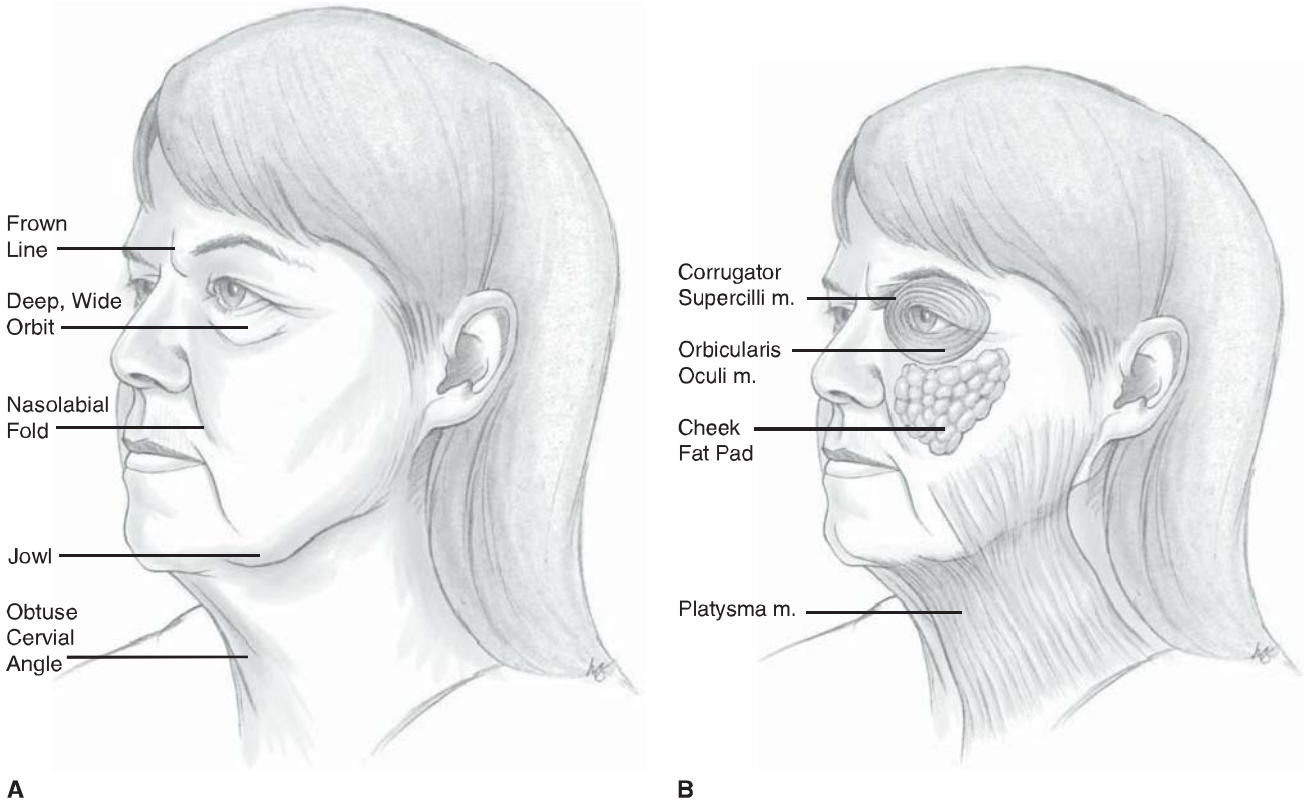

Figure 188.1 **A:** Topographic changes seen in the face with aging. **B:** Underlying soft tissue and muscular changes seen in the aging face. (Adapted from Zimbler MS, Kokoska MS, Thomas JR. Anatomy and pathophysiology of facial aging. *Facial Plast Surg Clin North Am* 2001;9:179–187.)

these changes. In this regard, it is convenient to think of skin aging in terms of extrinsic and intrinsic factors, affecting both the epidermis and the dermis (6). Extrinsic factors refer to environmental insults such as sun-induced damage (photodamage). Intrinsic aging refers to the natural effects of time and is generally characterized by tissue atrophy and descent and reduction in skin cellular and protein components. In fact, chronologically aged skin has reduced epidermal thickness, flattening of the dermal–epidermal junction, atrophy of the dermis, and a general decline in a variety of cell populations including melanocytes and Langerhans cells (7). This epidermal thinning then makes the skin more susceptible to damage from shearing-type forces (6). Moreover, Yousif and Mendelson (8) showed how habitual facial expressions lead to coarse skin wrinkling and deep folds. However, Kligman et al. (9) noted that in point of fact, there are no histologic features that distinguish the various types of wrinkles from the surrounding skin. He noted that instead there is a configurational change that results from mechanical stress acting on lax, excessive skin, especially in actinically damaged regions.

On the other hand, photoaged epidermis is characterized by striking variability: in its thickness, with alternating areas of atrophy and hyperplasia; in pigmentation, with alternating lentigines and depigmented areas; in the degree of nuclear atypia; and in orderliness of keratinocytes maturation (10). In the past, sun-damaged epidermis was thought to be characterized by a reduction in structural elements, leading to skin wrinkling. In fact, the most striking feature of photodamaged skin is the presence of large quantities of thickened, poorly organized degraded elastic fibers, which degenerate into an amorphous mass, better known as elastosis. This loss of elastin decreases skin elasticity, defined as the loss of the ability of the skin to recoil and redrape once pulled away from the deep tissues (11). The result is aged skin, which does not retain moisture and which loosens and hangs. The ground substance component of the dermal connective tissue matrix is greatly increased. In the dermal cell population, photodamaged skin shows numerous, hyperplastic fibroblasts and abundant, partially degranulated mast cells, which result in a chronic low-grade inflammation termed heliodermatitis. Finally, photodamaged skin shows extensive changes in the microcirculation, which can affect flap viability. Along with skin changes, atrophy of underlying soft tissue and fat have also been described. Skeletal changes pertaining to both bone loss and bone remodeling also occur with aging.

Overall the aging face can be viewed as a coupling of redistributed ptotic underlying soft tissue with overlying skin changes. Together, these changes combine to contribute to the overall impression of the aging face. For most aging face patients, this means that facial rejuvenation will necessitate the surgeon concentrating on five points of interest: (a) the jowl, (b) the deepened melolabial and nasolabial folds, (c) the neck, (d) the malar region, and (e) the skin itself.

SURGICAL ANATOMY

The last 20 years have brought about numerous improvements in the face-lift surgery. These new advances have largely come about through better anatomical understanding as well as an understanding of how the aging process alters these anatomical components throughout the face and neck. Certain salient points of the facial anatomy for rhytidectomy, including vascular supply, details of the SMAS and its relation to the facial nerve, as well as the presence of retaining "ligaments," are described here.

The facial skin is supplied by branches of the external carotid artery. Specifically, the superficial temporal artery, facial artery, transverse facial artery, and infraorbital artery anastomose with one another in the subdermal plexus. The internal carotid artery also contributes to the facial skin centered around the radix and the glabella through branches of the ophthalmic artery. However, this area is not routinely addressed during face-lifting. The elevated subcutaneous flap is based solely on the subdermal plexus, which is supplied by muscular cutaneous arteries arising from branches of the facial and infraorbital arteries. Unfortunately, the standard subcutaneous and SMAS two-layered face-lift effectively divides the skin from its underlying perforating branches. A recent study comparing the vascular anatomy of basic skin flaps in the subcutaneous and SMAS rhytidectomy, the composite rhytidectomy, and the subperiosteal rhytidectomy found, not surprisingly, that the best blood supply was found in subperiosteal dissection while the most tenuous supply was in the subcutaneous flap (12). However, outside of smokers and those patients with small vessel disease, one must consider that each of these techniques has been used for many years with minimal low flap perfusion rate complications (5).

Perhaps the first, and most important, development in the evolution toward the present-day rhytidectomy was the description of the SMAS. In fact, while the precise boundaries of the SMAS continue to be a source of debate, the significance of this fascial layer in relation to present-day rhytidectomy is unquestionable. The SMAS, which is a fibromuscular fascial layer, invests and interlinks the muscles of facial expression. Moreover, in this function it maintains consistent relationships with the facial nerve and major vessels within the facial region. For the operating surgeon, mastery of these relationships and planes of dissection are therefore critical (13).

The regional variations that are found in the relationship between the SMAS and the neurovascular structures are most profound when examining the SMAS and the facial nerve above the zygoma versus below the zygoma (14). Specifically, in the temporal region above the zygoma, the superficial temporal artery and frontal branch *course through the SMAS* (also called temporoparietal fascia). Below the zygoma, the SMAS fans out over the parotid gland and then above the masseter muscle before it surrounds the facial mimetic muscles. Therefore, in the lower face, the facial nerve branches are always *deep to the SMAS* and innervate the facial mimetic muscles on their undersurface (Fig. 188.2).

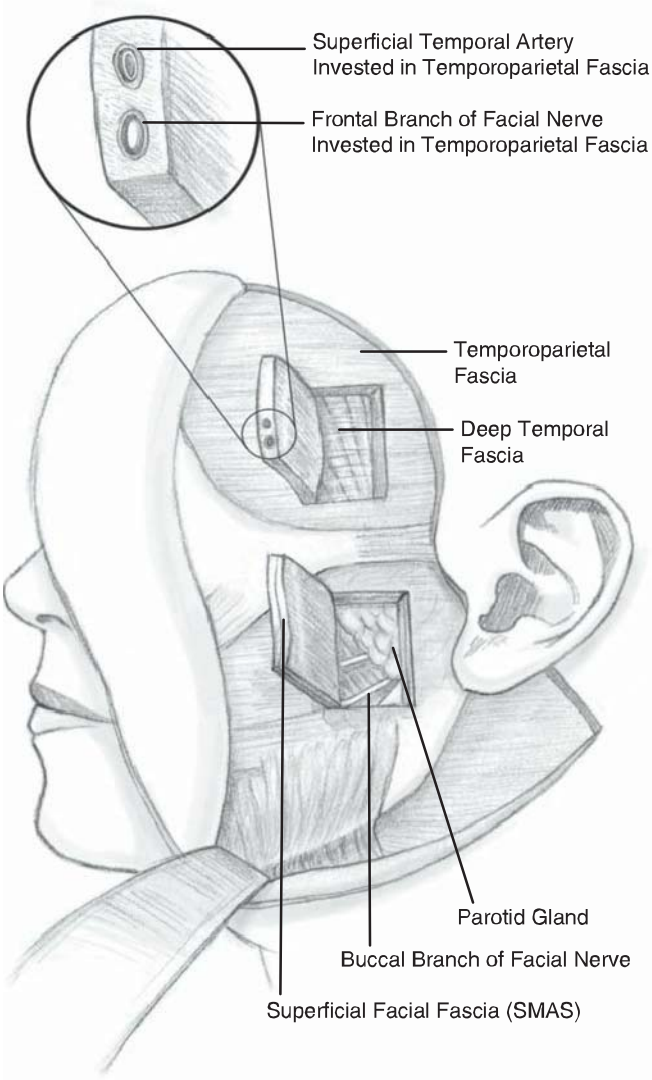

Figure 188.2 In the temporal region, above the zygoma, the frontal branch travels through the SMAS. In the lower face, below the zygoma, the facial nerve branches lie deep to the SMAS and innervate the facial mimetic muscles from their deep surface. (Adapted from Stuzin JM. The relationship of the superficial and deep facial fascias: relevance to rhytidectomy and aging. *Plast Reconstr Surg* 1992;89(3):441–449.)

However, there are three exceptions to that rule. The levator anguli oris, buccinator, and mentalis muscles lie in a somewhat deeper plane making their innervation from the facial nerve from their superficial surface, rather than their undersurface. It should be noted that even in the deep plane and composite lifts, the dissection medial to the zygomaticus major and minor is actually above the SMAS because the SMAS thins out over this region. Moreover, it should be noted that a significant, distinct myofascial layer superficial to the parotid fascia is not always clinically apparent. In fact, Jost and Levet (15) have suggested that the SMAS overlying the parotid includes what the authors have otherwise distinguished as the parotid fascia.

Finally, as previously alluded to, the SMAS has been noted to have a number of "ligamentous" supports, which make it adherent at specific points to the overlying dermis

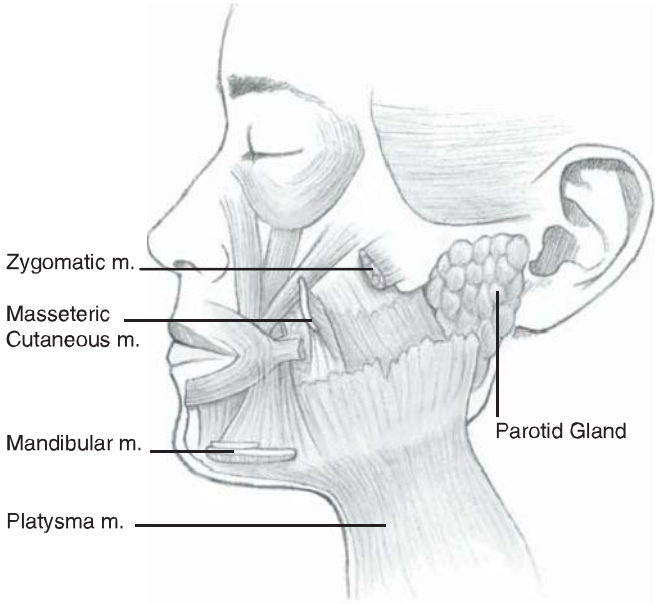

Figure 188.3 The four retaining ligaments of the cheeks.

and underlying muscular/osseous attachments. Specifically, four ligaments support the soft tissues of the cheek: (a) the parotidomasseteric ligament, (b) the platysmal auricular ligament, (c) the zygomatic ligament (McGregor patch), and (d) the mandibular ligament (Fig. 188.3). Although not true ligaments, these fascial condensations are especially important in the deep plane and composite rhytidectomy (16). Release of these ligaments is important and will allow the surgeon to achieve a better pull to redrape the tissue. However, this task must be undertaken with extreme caution as branches of the facial nerve are in close proximity.

SURGICAL EVOLUTION: A HISTORICAL PERSPECTIVE

A steady evolution of anatomically derived technical advances has occurred in the rhytidectomy procedure since the early days of simple skin flap advancement. Reports of face-lifting attempts date back to the very first years of the 20th century and consisted primarily of skin excision and direct closure. This technique was utilized for over 50 years before the first major contribution to advance face-lifting was provided by Skoog. Sometime in the mid-1960s, Skoog began to elevate a "complex morphologic unit" in the cervical region and advance it posteriorly (17). It was observed that this "two-layered shift" of the cervical fascia corrected the anterior banding of the neck and the redundant skin of the cervical region. Skoog subsequently followed this with his description in 1974 of his technique of superficial rhytidectomy of the face and neck based on a subfascial dissection. The new era in face-lift surgery had begun (18–20).

It would take until 1976 before Mitz and Peyronie (21) defined the "complex morphologic unit" referred to by Skoog as the SMAS. The SMAS lift approach, which then became vogue, was a significant step in the evolution of the

present-day rhytidectomy. However, some surgeons, in pursuit of the ideal lift, still found the results of the SMAS lift to be short-lived and complicated by perioperative problems. For some surgeons, the SMAS lift did not appear to sufficiently address the ptotic midface and melolabial fold region. In an effort to enhance midface tissue, Faivre (22) described in 1988 the deep temporal face-lift in the sub-SMAS plane. That same year, Psillakis et al. (23) described the subperiosteal midface lift to correct ptotic malar fat pad. In 1990 and 1992, Hamra (24) published his techniques on deep plane face-lift and composite face-lift, respectively (25). In the deep plane face-lift, Hamra innovates on the Skoog technique by adding a superolateral elevation of the malar fat pad. The composite lift added dissection and resuspension of the orbicularis oculi muscle superomedially, thus effacing what the author has termed as the malar crescent, in an effort to rejuvenate the periocular complex and better create harmony with the lower parts of the face.

Recently, many "newly named" face-lift techniques have been heavily marketed: the mini-lift, weekend lift, short flap lift, S lift, and lunchtime lift. Most of these lifts rely on a short skin flap and sometimes a minimal SMAS suspension. These less invasive procedures have the advantages of decreasing associated complications and substantially minimizing patient recovery time. However, in most cases their indications are limited to patients with limited signs of aging, and results from such techniques may be short-lived or less than ideal. Webster had explored short flap face-lifting in 1983, which many later abandoned (26).

To date, it is uncertain what percentage of surgeons are performing the extended sub-SMAS lifts versus the traditional SMAS plication/imbrication techniques. Moreover, questions remain as to the superiority of the results that are achieved in the deep plane versus plication techniques. In fact, while anecdotal reports abound to this effect, it will be very difficult to accomplish the study that can definitively answer this and a whole host of other questions. Proponents of deep plane rhytidectomy claim an improved nasolabial fold in comparison to the traditional SMAS suspension techniques (27). Adamson et al. (28) found a twofold improvement with deep plane measured by the degree of increased volume at the malar eminence and by the amount of effacement of the fold. Becker and Bassichis (29) concluded that results from a deep plane face-lift were not superior to those from SMAS plication in patients that are younger than 70 years old. Baker (30) and Kamer (31) maintain reservations regarding the superiority of the results from the deep plane lifts, especially when these "implied benefits" are weighed in relation to the added risks to the facial nerve. Baker and Conley (32) notes that a review of the world literature in 1979 found an incidence of 0.01% permanent facial nerve injury in deep plane cases. He notes in a later paper (30) that the published articles on the new deep dissection techniques conjure concern as they report a relatively high incidence of facial weakness in the hands of extremely qualified surgeons. He questions what happens when these procedures are attempted by less experienced surgeons. Time and experience are still needed before the authors will know if the added work and increased potential risk for complication is worth the improved aesthetic results. In a recent systematic review of 39 articles comparing the efficacy and complication rate of different face-lift techniques, Chang concluded there was a lack of quality data to be objectively compared (33). It is also important to note that results will always vary from surgeon to surgeon due to skills and expertise.

ASSESSING CANDIDACY

With an understanding of the physiologic and anatomical changes that present with facial aging, the surgeon is ready to determine whether the patient is a candidate for facial rejuvenation surgery in general and rhytidectomy in particular. This evaluation includes surgical, medical, and psychological components.

The surgical criterion to be addressed is whether rhytidectomy will create physical changes in the patient's face that will contribute meaningfully to a more youthful appearance. In making this determination, it is helpful to divide the stigmata of facial aging into two categories: those that are improved by repositioning of facial tissues and those that require changes in the structure of the tissues themselves. In the first category, one would include ptosis in the jowl, submentum, and anterior neck leading to a disruption of the ideal youthful contours of the jawline, cervicomental angle, and neck, respectively. These are the primary areas improved by rhytidectomy. Malar ptosis will experience modest improvement as well.

On the other hand, intrinsic changes in the tissues themselves are not well addressed by rhytidectomy. As noted earlier, concomitant with the ptosis described above, aging brings about many changes in the skin itself. Fine lines and deeply etched wrinkles in the skin are the grossly visible correlates of crevices in the dermis and subcutaneous tissues formed over time as a result of actinic damage, senescence of connective tissues, and habitual facial expressions. These cosmetic defects will be minimally improved, at best, by rhytidectomy. Instead, they can be addressed more directly by resurfacing techniques, including both chemical and laser exfoliation. In the situation in which such intrinsic properties of the skin comprise a significant portion of the aesthetic problem, the patient should be encouraged to consider skin resurfacing as an adjunct or, in some cases, an alternative to rhytidectomy.

Once the surgeon has determined that a rhytidectomy will address the patient's aesthetic concerns appropriately, it is imperative to assess medical candidacy for the procedure. Most patients who seek cosmetic surgery are in good health, so medical contraindications to the proposed procedure are rarely seen. Vigilance is essential for avoiding disaster. Face-lift candidates—people who feel young inside and want their outward appearance to mirror that vitality—are exactly the same people who tend to minimize medical complaints and even may forget to relate serious medical problems

unless questioned directly. Significant bleeding diatheses and American Society of Anesthesiologists (ASA) class IV or V, in which a patient has a dangerously compromising medical condition, should he considered absolute medical contraindications to rhytidectomy. A patient in ASA class III, in which a medical condition impairs the patient's activities to some degree, should be approached with great caution. The severity of the condition and its potential impact on the safe conduct of the operation should be explored in detail. Conditions that may adversely affect healing including uncontrolled diabetes, diseases requiring chronic steroid therapy, or connective tissue abnormalities like the Ehlers-Danlos syndrome should be considered strong relative contraindications to face-lift surgery. Consultation with the primary care physician may be necessary to coordinate prescription medication regimens and facilitate the management of relevant medical conditions.

On the other hand, there are no age limitations for face-lift surgery, and age should not be a reason to deny surgery if the patient is in otherwise good health. A healthy patient in his or her late 70s or early 80s may have 15 or 20 more years of quality life ahead, and the desire to have an improved appearance is indeed valid.

Finally, but not least important, an accurate assessment of the patient's psychological status is central to determining patient candidacy. The surgeon should determine patient motivation and attempt to ascertain whether the patient might fail to view a successful surgical outcome favorably or might react inappropriately to any aspect of the surgery. A thorough discussion of the patient's goals and objectives should provide important clues to his or her psychological profile (34). Although many patients are unaware of exactly what surgery can and cannot accomplish, others have clearly unreasonable expectations, which can include looking exactly as they did 10 or 20 years ago, having surgery without scars, requesting an unnaturally tight lift, or attempting to obtain promises and guarantees. Patients who are excessively occupied with minute flaws also may be poor surgical candidates. Moreover, patients who have recently undergone a major change in their personal status, such as the death of a loved one or divorce, may be subject to depression or psychological unevenness and may require special care.

PREOPERATIVE EVALUATION AND PLANNING

General Considerations

Once a patient is deemed an appropriate candidate for rhytidectomy, they need to be educated clearly before surgery. They must understand that rhytidectomy helps with excessive skin and jowling and provides for redraping of the skin, but it does not change the quality of the skin itself. If fine or deep rhytids are present preoperatively, they will be present postoperatively as soon as the swelling goes down. In severely sun-damaged patients, full-face deep chemical peeling with phenol solution or CO_2 laser resurfacing is often necessary as an adjunct and can be done several weeks after the initial face-lift surgery. If there are significant rhytids limited to the perioral or periorbital areas, these cosmetic units may be safely peeled or removed by laser simultaneously with the rhytidectomy as long as these areas are not undermined during the procedure. Undermined areas are partly devascularized in the immediate postoperative period and further skin insult by laser resurfacing could lead to skin necrosis.

To assess further the overall improvement possible with rhytidectomy, the underlying structure of the face must be critically evaluated. Patients who had a good bony structure of the cheekbones, chin, and jaw during their youth will have the best results, as the redraping of skin will help to highlight these attractive bony structures. Therefore, patients who have a thinner, angular face and good bony definition are generally much better candidates than patients with rounder faces, low cheekbones, or a short mandible (Figs. 188.4 to 188.6).

Adjunctive chin and submalar cheek augmentation may be necessary in conjunction with a face-lift to achieve the desired result. Patients who have a retrusive chin cannot get desired cervicomental definition without a chin implant, even after a face-lift. Also, because the aging process sometimes causes a hollow-cheek deformity due to the atrophy of soft tissue and fat with ptosis of the fat pads, older patients sometimes require submalar augmentation or resupport of the fat pads simultaneously with the face-lift. Redraping the skin alone will not replace soft tissue cheek hollowness.

As the underlying structures of the face dictate the aesthetic results possible above the jawline, those in the neck similarly limit the outcome there. In particular, the position of the hyoid bone relative to the mandible varies from patient to patient. This relationship defines the course of the suprahyoid musculature of the floor of the mouth and limits the maximum improvement possible in the cervicomental angle. A relatively high and posterior hyoid is ideal, allowing maximum elevation of the submental contour and the greatest definition between the submentum and neck in profile. A relatively low and anterior hyoid limits the possible improvement in this area to a predictable degree. It is mandatory, therefore, that hyoid position be assessed and its effects on the possible outcome discussed with the patient in a way that is easily understood. The authors have found the use of diagrams illustrating hyoid position to be very helpful in their practices (Fig. 188.7).

A full evaluation of the facial nerve and muscles should be done preoperatively, particularly noting any asymmetries, especially around the mouth. Sometimes patients have asymmetric smiles or may inadvertently elevate the brow. There may be static asymmetries as well, ranging from minor unilateral cheek or jowl fullness to generalized asymmetry as in hemifacial microsomias. Any asymmetry should be documented, photographed, and discussed with the patient before surgery, or the patient may attribute their asymmetry to the surgery (35). Further, it gives the surgeon the opportunity to

Figure 188.4 Excellent candidate for a face-lift: little fat, good bone structure, and not too much skin.

Figure 188.5 Postoperative views of same patient after face-lift and upper eyelid blepharoplasty.

point out that minor asymmetry is normal and that perfect symmetry cannot be a surgical goal. The surgeon also should note any traumatic facial and neck lacerations, sites of previous biopsies, acne scars, facial or neck scars, subcutaneous depressions, surface irregularities, and focal lesions.

Generally, the older patient who presents with voluminous sagging skin or the patient with a fat face and neck would not be as good a candidate as the thinner 40- to 50-year-old patient because postoperative skin re-draping with such excess is less satisfactory, especially if elastosis is present. Such patients should be advised that for a better result, a tuck procedure may be necessary 6 months to 1 year after all the retraction has occurred from the original face-lift (36). If liposis is limited to the submental area, the patient will be a better candidate than one who has a full, rounded face with fat throughout. Liposuction in conjunction with a face-lift exerts its maximal effect in the submental area.

Similarly, if a patient contemplates a weight loss of more than 10 pounds, it may be better to postpone surgery until afterward. The authors discourage patients who have a history of repeated weight gain and loss from considering face-lift surgery because repeated stretching of the facial skin may cause a premature return of skin laxity.

Smoking history is also particularly relevant. Rees and Aston (37) noted that smokers have 12 times greater risk of skin slough than nonsmokers, possibly secondary to vasoconstriction, and also have a higher incidence of hematoma formation. Postoperative coughing may contribute to this complication. Smoking has long-term effects on the skin that cannot be completely erased by simple cessation perioperatively. If the patient stops smoking for 1 month before and after surgery, many potential complications associated with smoking can be limited. However, even with smoking cessation 1 month prior to surgery, superficial epidermolysis in the preauricular area is not infrequent. Moreover, these patients very likely would be better candidates for a deep plane face-lift in order to limit these possible complications.

Patients with a history of excessive alcohol intake may have characteristic nutritional or liver deficiencies that may lead to poor surgical healing. They also may be uncooperative in the perioperative period, when alcohol consumption is not allowed. Be alert for physical findings associated with excessive alcohol use and hepatic insufficiency.

PREOPERATIVE PREPARATION

Full-disclosure informed consent for surgery and photographs are obtained. The patient is given a packet that includes preoperative and postoperative instructions and a

Figure 188.6 A less-than-ideal candidate for a face-lift: excessive skin and fat and rounded bony contours.

description of what to expect during recovery. Having the patient fill all prescriptions in advance serves two purposes: It removes the distraction of a rushed visit to the pharmacy for the patient and caretakers in the early postoperative period when even simple things can be difficult. Also, it allows the patient to take antibiotics the night before surgery to assist in preventing infection and provides the patient with sedatives should sleep be difficult the night before surgery.

The patient is urged to stop smoking 1 month prior to surgery. All medications containing aspirin, steroids, nonsteroidal anti-inflammatory agents, and vitamin E, as well as all herbal medications, should be discontinued at least 2 weeks before surgery. If there is a history consistent with a bleeding diathesis, however tenuous, preoperative bleeding time, platelet count, prothrombin time, and partial thromboplastin time or other coagulation studies should be ordered. The goal is avoidance of hematoma, the most common complication of rhytidectomy.

SURGICAL PLANNING

Successful face-lift surgery is achieved through thoughtful planning and execution of every aspect of the procedure (38). The amount of actual skin excised, the tightness and completeness of the lift in the cheeks, the ability to contour and resuspend the neck, the smoothness of the submental region, and the degree to which the incisions can be camouflaged all are important considerations in achieving a natural, nonoperated appearance. Rhytidectomy is an operation of compromises.

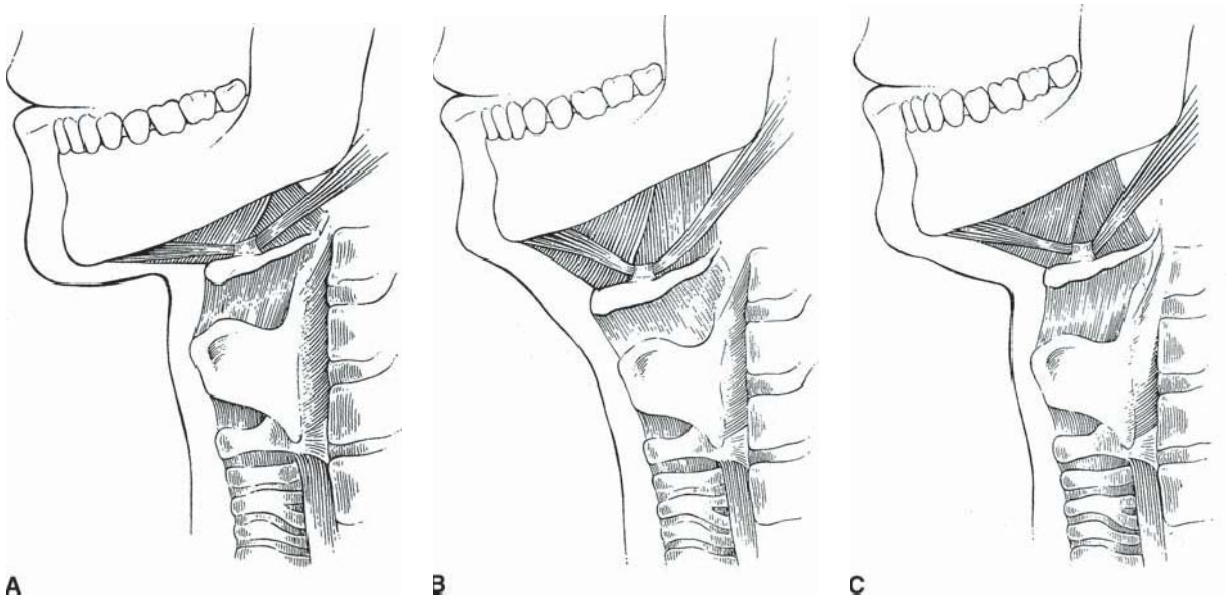

Figure 188.7 Schematic representation of the limits of improvement in the cervicomental contour imposed by the underlying hyoid bone and suprahyoid musculature. A high posterior hyoid is most favorable for face-lifting **(A)**, and a low anterior hyoid is least favorable **(B)**; most patients fall somewhere in between **(C)**. Anesthesia

The authors prefer to perform face-lifts with the patient under general anesthesia in a hospital ambulatory setting or outpatient surgical center (39). Many patients prefer the idea of complete somnolence and amnesia and are relieved of any anxiety concerning positional discomfort or surgical pain. The presence of an anesthesiologist permits monitoring of the patient's vital signs and status and allows the surgeon to concentrate on the events in the operative field. Communicating any special needs with the anesthesia professionals greatly facilitates the entire operative and postoperative course. The draped endotracheal tube can be moved side to side and does not interfere with the procedure. The anesthesia team strives for rapid, effective anesthesia with a smooth and deep emergence phase coupled with a relatively rapid recovery. Smooth extubation must be guaranteed, as bucking on the endotracheal tube may predispose the patient toward hematoma formation. No long-acting muscle-relaxing agents are permitted, to allow proper intraoperative facial nerve monitoring. Pre-dissection infiltration of local anesthesia with epinephrine is utilized for improved hemostasis. The authors prefer to have the patient emerge from anesthesia after the dressing is in place: this seems to facilitate dressing placement and allows optimal gentle pressure on the skin flaps to decrease the risk of hematoma formation further.

Marking

With the patient in the sitting position, the surgeon better appreciates the descended tissues and the effects of gravitational forces. This helps prevent judgmental errors regarding the amount of fat removal, the degree of laxity, and the amount of SMAS suspension required (40). Markings generally serve two main purposes. On one hand, they help outlining on the skin the areas and the severity of descended tissue, including skin and deeper subcutaneous soft tissue such as SMAS and fat. Attention is precisely drawn to the lower third of the face around the jowl area and the mandibular line. Also the neck is marked for fullness and skin laxity blunting the cervicomental angle as well as for vertical platysmal bands closer to the midline. Weak platysmal bands can be seen best with the patient upright. The patient is asked to jut the lower jaw forward and asked to grimace, and the platysmal bands may be demonstrated more easily. Other important anatomic landmarks to be marked include the anterior borders of the sternocleidomastoid muscles, the submental crease, the region of jowl formation, the angle of the mandible, the inferior mandibular border, and the geniomandibular groove. On the other hand, the authors use markings to delineate our farmost limit of dissection to avoid unnecessary and perhaps dangerous dissection over specific areas. Also it is important to trim hair around the markings before proceeding to the incisions. This will prevent hair from trapping in the incision lines when performing the closure. Hair is pulled away from the incision lines using rubber bands, and clear sticky drapes are placed to maintain hair position out of the surgical field.

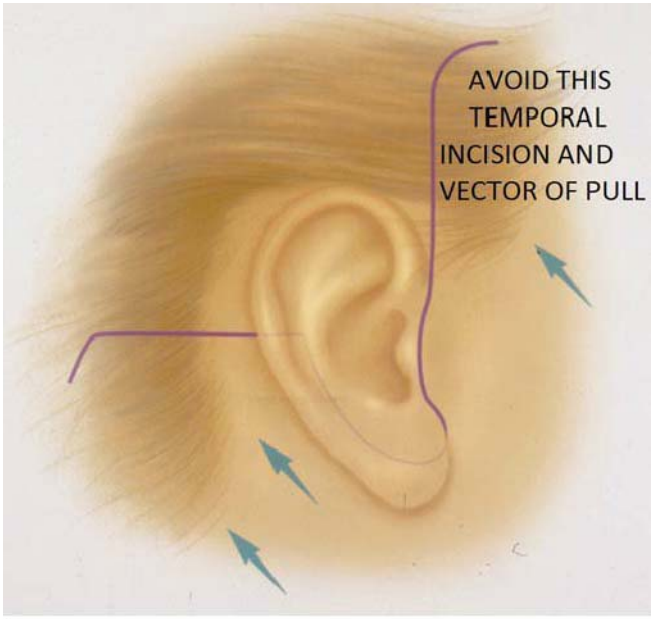
Incisions

While much of the recent literature on rhytidectomy describes techniques for improving the quality of the face-lift, far less attention has been devoted on detailing the means of avoiding visible incision lines (41). In fact, while patients present with an interest in facial rejuvenation, rarely would they pursue these goals at the price of visible incision lines.

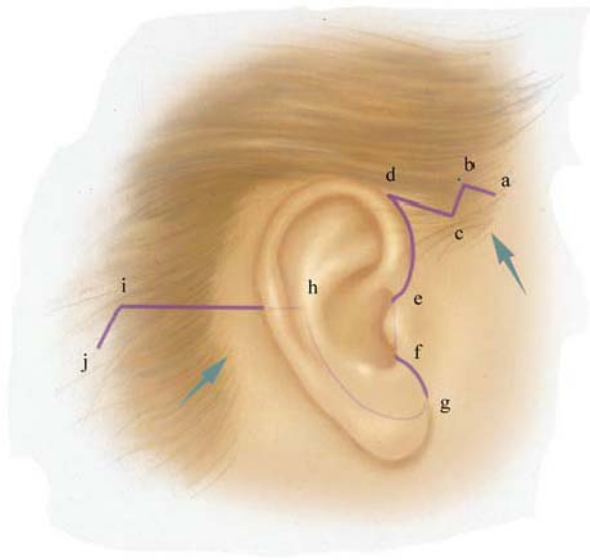
Several factors can influence incision location, but the authors have found that the most important variable is appreciation for the importance of preserving the temporal hair tuft and the posterior hairline in the female patient. The temporal region is key because a poorly designed and executed incision in this area can lead to temporal alopecia (Fig. 188.8). Descriptions of many of the classic face-lifts include a vertical preauricular incision that enters the temporal scalp posterior to the sideburn hair and then angles forward in a curvilinear fashion. The redraping of the anterior facial skin into the temporal sideburn then creates an area of hair loss. This obvious, unwanted sequela of face-lift surgery results from lifting and removing the natural temporal hair tuft. It is especially apparent in patients requiring a relatively large amount of skin removal from this region, who may already have thin, light-colored hair and a high tuft preoperatively. Unfortunately, no salvage face-lift procedure can improve this complication, which is remedied by hair flaps or follicular unit hair transplantation.

To avoid this problem, the authors use a temporal hair tuft–sparing incision (41) (Fig. 188.9). The incision begins horizontally no higher than the level of the supraauricular crease (segment c to d). As it extends horizontally, the incision has a vertical limb (segment b to c) followed by

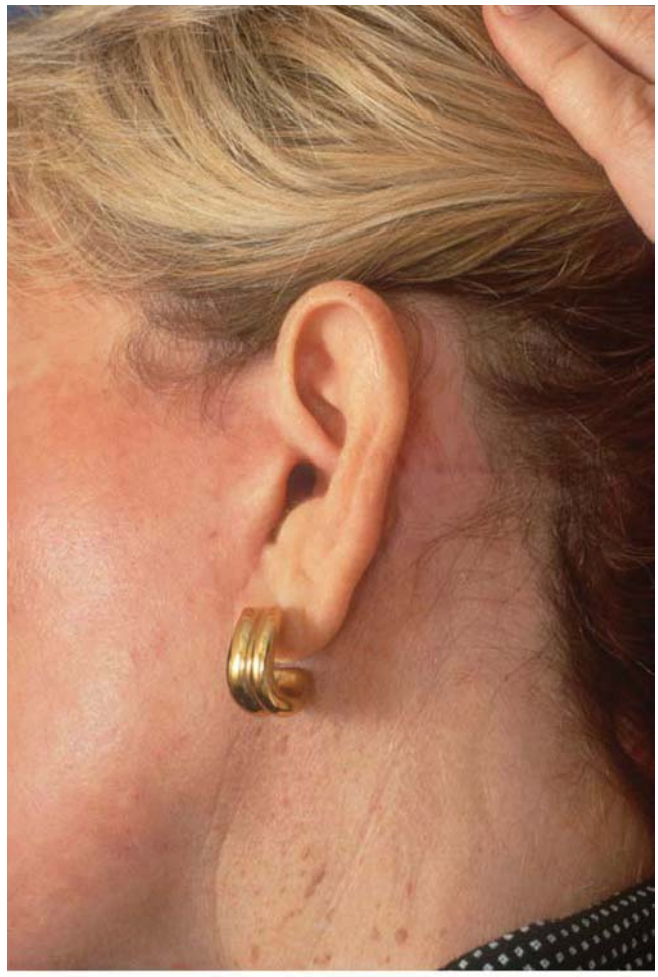
Figure 188.8 This patient had a face-lift performed elsewhere, with improperly placed incisions that caused temporal alopecia, a visible pre-auricular incision, and a post-auricular step-off in the hair line.



A



B



C

Figure 188.9 **A:** Schema of a poorly planned female face-lift incision performed elsewhere still seen too often; the temporal portion of this incision should be avoided in women because skin excision after a posterosuperior pull leads to loss of the temporal hair tuft and a post-auricular posterior superior pull on the flap causes a hairline step-off. **B:** Schema of our incision with various segments labeled. Note the anterior superior vector for skin re-draping post-auricularly that realigns the hairline. The incision is hidden in the hair, not at its edge. **C:** Postoperative result of a typical patient with our incision showing no temporal hair tuft loss and well-concealed pre- and postauricular incisions. (Reprinted from Kridel RWH. Techniques for inconspicuous face lift scars. *Arch Facial Plast Surg* 2003;5:323–333, with permission.)

an anteroinferior limb (segment a to b) to accommodate any excessive skin reduction and prevent tissue coning. To avoid visibility of this incision, the angle of the first horizontal portion closest to the ear is designed to bevel across the hair follicles; thus, even if there is no hair below this line, the hair follicles above will grow though the advanced lower facial skin flap and hide the scar. The more anterior vertical hair tuft (segment b to c) and then horizontal limb are made parallel to the hair follicles to avoid alopecia (Fig. 188.10). For each segment of this temporal incision, attention must be paid to the direction of beveling.

Several alternatives for the posterior occipital incision must also be carefully considered. Whereas an incision along the inferior edge of the postauricular hairline completely preserves the existing hairline and simplifies redraping, postoperative widening of the scar or potential tissue loss makes this choice less desirable and requires the patient to wear the hair longer to camouflage the scars. Moreover, these patients can no longer wear their hair up because of the conspicuous scars.

Incisions that curve high into the postauricular area are completely hidden; however, potential flap necrosis and derangement of the hairline call for a compromise regarding the placement of the posterior incision. The authors prefer a horizontal incision that extends posteriorly into the hair from slightly below the midconchal region. However, in placement of this incision the authors take into consideration the spacing from the ear to the beginning of the posterior hairline. The incision extends about 5 cm and angles inferiorly at the distal end to reduce the potential cutaneous cone (dog ear) after flap rotation. This incision allows for an anterior vector during redraping maximizing the amount of hairline that is preserved. With experience, these postoperative posterior hairlines look quite full and natural. Respect and consideration for the patient's existing hairline and hair-bearing tissues pay great dividends in terms of patient satisfaction.

Additional factors regarding incision placement involve differences between incision done in men and women, especially in the preauricular limb, but also in the earlobe and postauricular areas (42) (see "Male Face-Lift").

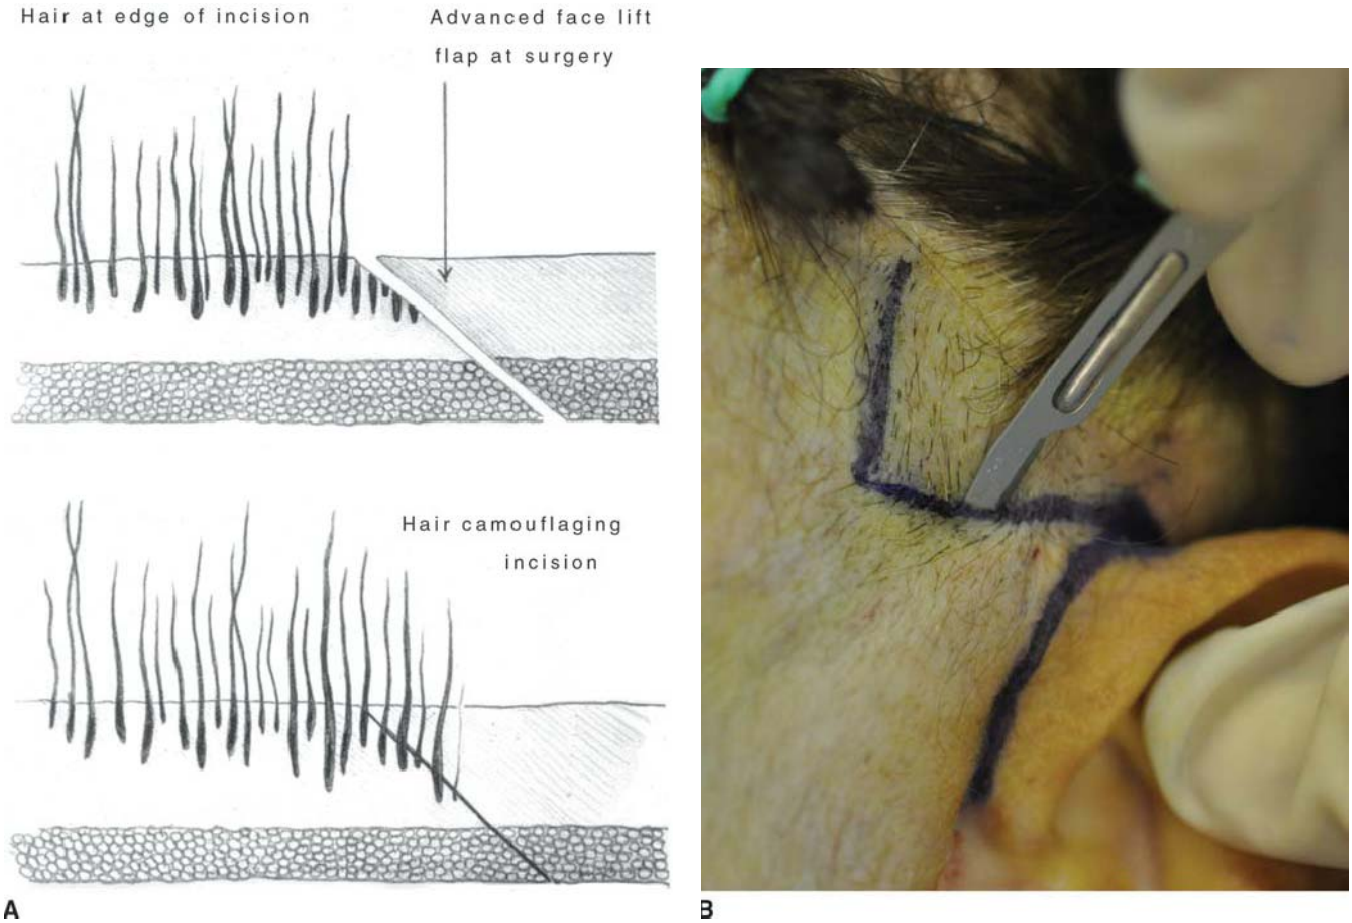


Figure 188.10 **A:** Beveling of incision *perpendicular* to hair shafts allows hair to grow through the advanced skin flap. **B:** Intraoperative view of incision beveled *perpendicular* to hair follicles. OPERATIVE STAGE

The classic, now outdated, face-lift procedure involves only the development of facial skin flaps and the redistribution and excision of excess skin (12). Undermining of the skin in the single-layer skin flap is usually extensive. This older technique is effective; however, the single-layer skin closure often places greater tension on the tissues and results in wider scarring or possible tissue loss. Theoretically, the skin-only, long-flap face-lift may not be as long-lasting and could predispose toward an increased risk of postoperative bleeding.

Contemporary facial plastic surgeons use either the concept of the two-layer cervicofacial rhytidectomy with suspension of the SMAS or the extended sub- SMAS/deep plane rhytidectomy (43). As already discussed, while many surgeons feel that the deep plane lift gives more long-lasting results and decreases the incidence of hematomas, there are as of yet no definitive studies to confirm these findings. In fact, while one study attempted to compare "deep plane versus superficial musculoaponeurotic system plication" face-lifts, Baker noted that many questions remain unanswered (25,44). As such, the authors will proceed with a brief descriptive outline of both procedures.

After appropriate marking of the patient and initiation of general and infiltrative anesthesia, the submentoplasty is performed.

Submentoplasty

The term submentoplasty encompasses submental lipectomy and platysmaplasty, as well as limited skin resection from the submental area on rare occasions. In both the SMAS and sub-SMAS rhytidectomy, surgeons have incorporated the use of suction-assisted lipectomy and platysmaplasty (40,45,46). The two-layer SMAS suspension technique and liposuction has numerous advantages. Open liposuction under direct surgical vision permanently removes fat cells and recontours difficult facial areas, such as the jowl and periparotid region. To gain the maximum improvement in the neck, most patients should undergo platysmaplasty at the time of face-lift. Most patients who are candidates for face-lift also have ptosis of the anterior platysma causing banding. This problem is best handled by low division of the offending bands and resection of the excess muscle under direct vision. Also, unlike the musculature of the face, the platysma of the neck is naturally dehiscent in the midline, with only a tenuous fascial connection between the paired muscles. In the absence of midline platysmal plication, SMAS suspension pulls the anterior margins of the platysma laterally, actually weakening support for the submental fat. Plication of the anterior margins resists this lateral migration and allows suspension to strengthen submental support and enhance recontouring of the neck. Finally, in most patients, a significant proportion of the excess submental fat is actually in the anatomic submental triangle, deep to the platysma, and therefore not accessible by closed liposuction. In these cases, the platysmaplasty approach allows access to this area, with direct open lipectomy. It has been our experience that the addition of routine platysmaplasty to rhytidectomy has both enhanced results in the neck and increased the duration of the aesthetic improvement (Figs. 188.11 and 188.12).

A horizontal incision 1.5 cm long is made in the submental crease. Sharp dissection is used to start a plane just below the dermis. Next, a double-lumen blunt-tipped liposuction cannula is advanced radially to form an even subcutaneous pocket in the submental/cervical region. Then the cannula is advanced, with the lumen toward the deep tissues at all times, in a back-and-forth fashion. Fat is suctioned from the previously delineated areas. Dissection is facilitated by tenting the skin upward and using a rapid motion, which avoids suctioning in the same area for too long. Aggressive suctioning in one position might create dimples and irregularities. Using the "pinch and roll" technique of palpation of the skin between the thumb and forefingers, it must be ensured that no excessive fat deposits are inadvertently omitted during this part of the procedure. Liposuction is carried inferiorly over the hyoid and toward the thyroid notch, then laterally to overlap the anterior borders of the sternocleidomastoid muscles, and then superiorly to the dependent portion of jowl formation and the edge of the mandibular border (Fig. 188.13).

The submental, subcutaneous pocket is inspected with the assistance of a fiberoptic headlight and a modified Converse retractor looking for individual neurovascular septations and controlling any rare bleeding points by using suction cautery. The anterior borders of the platysma are then identified and a small amount of horizontal sectioning is performed of the platysma at the level of the thyroid notch. If fat is found to be excessive between the medial edges of the platysma, one could do a direct lipectomy with the scissors. Staying midline and avoiding undermining the platysmal edges is important. The anterior borders of the platysma are then reapproximated in the midline using a corset platysmaplasty of 2-0 Vicryl suture. At all times, the vector of force is medial and superior. The plication is at least to the level of the hyoid; however, care is taken to avoid excessive tightening, which can strangle the sutured muscle. Also one should perform big enough bites to provide adequate tensile strength without being overaggressive and creating bunching that leads to a nondesirable central band.

The submental incision is left open until the end of the lift to provide access for inspection and further cautery as needed. Only after both flaps have been elevated, trimmed, and sewn into place should the submental incision be closed. This also allows for conservative submental cutaneous resection on rare occasions when excess is substantial

even after flap redraping laterally and posteriorly. The authors prefer a layered closure, using 5-0 plain for the subcutaneous layer and 6-0 Prolene in a running locking manner for the skin.

Flap Elevation

Next, beginning on one side, the previously delineated incision is made. Dissection is started occipitally, and the skin flap begun using face-lift scissors. With the scissors tips pointed upward, a gliding motion is used to develop the skin flap (Fig. 188.14). Upward direction of the scissors helps the surgeon better visualize the extent of the dissection. The authors believe that gliding motion rather than spreading prevents stretching trauma to blood vessels and decreases the incidence of telangiectasia encountered in the postoperative period. The skin may be densely adherent to the sternocleidomastoid fascia and the mastoid fascia, and meticulous superficial dissection in this area serves to elevate the flap without injury to the greater auricular nerve. The earlobe is dissected completely free and the skin mobilized over the tragus with small iris or serrated dissecting scissors. Because the temporal incision is placed to preserve the hair tuft, the plane of dissection should not be as deep as the temporalis fascia but rather just under the hair follicles. Superficial flap elevation in this region avoids injury to the frontal branch of the facial nerve, which crosses the zygomatic arch at this point.

Figure 188.14 Intraoperative use of face-lift scissors, with the skin retracted. Notice the tips of the curved scissors can be seen.

The authors usually develop a long flap in the neck and connect broadly with the submental preplatysmal dissection to allow optimal redraping of neck skin. Fat deposits are removed gently under direct visualization, and facial contouring is inspected for uniformity and desired appearance. The area is irrigated with saline to allow an enhanced visualization and better achieve hemostasis. Irrigation also cleans the wound from any free adipose tissue that underwent devascularization during dissection. The authors believe that this tissue would create an increased inflammatory response and prolong the healing phase if it remained in the surgical bed. Bleeding is controlled with bipolar cautery to avoid facial nerve or skin flap injury.

SMAS Suspension

After flap elevation, direct surgical management of the SMAS fascia is performed. SMAS suspension is the foundation on which the longevity, safety, and aesthetically pleasing result is built. SMAS suspension permits tension-free closure of the incision by transferring the strength and support of the face-lift rejuvenation to the deeper structures and tissues. SMAS suspension can be achieved by several different methods (47–50).

Imbrication techniques involve direct incision, resection, or undermining of the SMAS fascia with the reapproximation or overlap of the cut SMAS fascia edges. With imbrication methods, the SMAS is usually identified and incised within the region anterior to the tragus and below the earlobe, overlying the deeper parotid fascia. Many surgeons undermine a separate SMAS fascia layer and resect excess tissue after advancement and redraping. However, one should be careful when elevating two different flaps (cutaneous and SMAS) separately as vascular compromise might ensue if a large area is dissected. Proper suture placement buries each knot to prevent suture spitting or later palpation by the patient. An alternative imbrication technique involves excising a segmental portion of SMAS and resuspending the anterior cut layer without additional undermining. Increased sharp dissection associated with imbrication techniques increases the risks of bleeding, nerve injury, and skin slough. In patients with wide, chubby faces, imbrication and resection tends to flatten the region overlying the parotid gland and therefore may offer some advantages in early surgical definition of this region.

Plication techniques for SMAS suspension avoid direct cutting and undermining of the SMAS layer. The surgeon folds the SMAS fascia on itself and secures the newly folded tissues with permanent buried sutures. Because SMAS plication involves less dissection and surgical time, the potentially decreased risks are thought to offer some significant advantage over imbrication.

With either technique, SMAS suspension lifts and resupports the attached skin layer and reduces the amount of potential cavity space created during flap elevation. The question of which technique is better in terms of long-term results and decreased morbidity is controversial. Webster et al. (51) studied imbrication versus plication by performing each method on opposite sides of the face. By taking exact measurements and confirming the findings on fresh cadaver dissections, they concluded that there was no objective benefit favoring imbrication over plication during the surgical procedure. Subsequent studies failed to demonstrate any long-term advantages either. Because imbrication theoretically involves a greater chance for surgical morbidity, the authors prefer plication for SMAS suspension.

The direction of forces applied to the SMAS layer by sutures is important, and specific vector patterns are used routinely. Plication is done by tugging on the SMAS fascia in a bidirectional vector. Before placing any sutures, the effect of each tug on the face and neck should be noted and the desirable sites secured with 2-0 nonabsorbable sutures. Braided sutures are utilized in order to provide knot security without multiple ties, which can otherwise lead to palpable suture knots. Multiple buried sutures are placed along each vector to avoid relying on only one suture. The first suspension vector generally runs from the angle of the mandible to the fascia near the superior mastoid cortex. Suturing at this point affects the cervicomental angle and the angular bony contour of the mandible, which define a smooth jawline and neck. Attention is then turned to the second vector, which originates in the SMAS of the cheek and mandibular ramus near the anterior border of the parotid. The SMAS here is extended with a more superior than posterior vector toward the preauricular sulcus and tragus. Finally, the third vector extends from the posterior border of the cervical platysma in a predominantly superior direction to the sternocleidomastoid fascia in the region of the mastoid tip. Additional sutures are placed where required for even, firm plication. This is mostly performed around the parotid area to flatten the bumps created by plication sutures, creating a smooth and more natural result over the cheeks.

The overall direction of pull remains superior and only partially posterior (Fig. 188.15). A pull that is too posterior creates a distinctly unattractive and artificial appearance sometimes referred to as the lateral sweep. Posterior lifts tend to widen and flatten the oral commissure, resulting in a disproportionately large mouth. The standard rhytidectomy with SMAS suspension may fail to improve the nasolabial fold to a significant extent unless significant subcutaneous dissection is performed. The SMAS inserts on the mimetic muscles of the face (21). In the perioral area, these include the platysma and the same lip retractors and elevators discussed previously. SMAS suspension therefore results in further lateral and superior displacement of the perioral soft tissues, which are densely attached to the mimetic musculature with relatively little effect on the malar soft tissues, which at best are associated only weekly with the muscular plane. In isolation, then, the act of SMAS suspension theoretically could deepen the nasolabial fold even further. That it does not seem to deepen in practice likely results from the excision of excess skin performed after SMAS suspension. The greater the amount of skin excised, the more improvement in the fold. Because of preoperative skin laxity, it is generally possible to excise sufficient skin to result in a small net improvement in the fold without closing under undue skin tension and predisposing to skin slough or scar widening. However, it should be noted that placement of sutures, application of tension, and removal and redraping of skin are so individually variable that different surgeons will find widely disparate results while using the same overall technique.

Figure 188.15 *Arrows* indicate the direction of pull for SMAS plication.

DEEP PLANE LIFT

The SMAS suspension face-lift is a highly effective operation. With appropriate case selection and planning, both patient and surgeon can expect a technically sound surgery to produce very satisfactory results. However, cosmetic surgeons and their patients are very demanding groups. Therefore, innovative surgeons have continued to attempt

to improve the SMAS plication face-lift by doing deep plane/sub-SMAS face-lifts (31,52).

The primary areas of patient and surgeon dissatisfaction with generally accepted face-lift techniques have been the nasolabial fold, the inconsistency in achieving long-term results, and the occurrence of perioperative complications. The family of deep dissection rhytidectomies is aimed primarily at improving the nasolabial fold to a greater extent than is possible using widely accepted SMAS suspension techniques. Of the various techniques that have been reported (22,23,52), the deep plane or, more recently, composite rhytidectomy of Hamra has attracted the most interest. The key distinctions of deep plane rhytidectomy relative to the SMAS plication procedure described in detail already will be discussed and the theoretical advantages and disadvantages noted.

The deep plane rhytidectomy is in fact carried out at three different planes, depending on the area of the face and neck being dissected (31,25) (Fig. 188.16). The dissection of the neck (inferior to the jawline) is preplatysmal

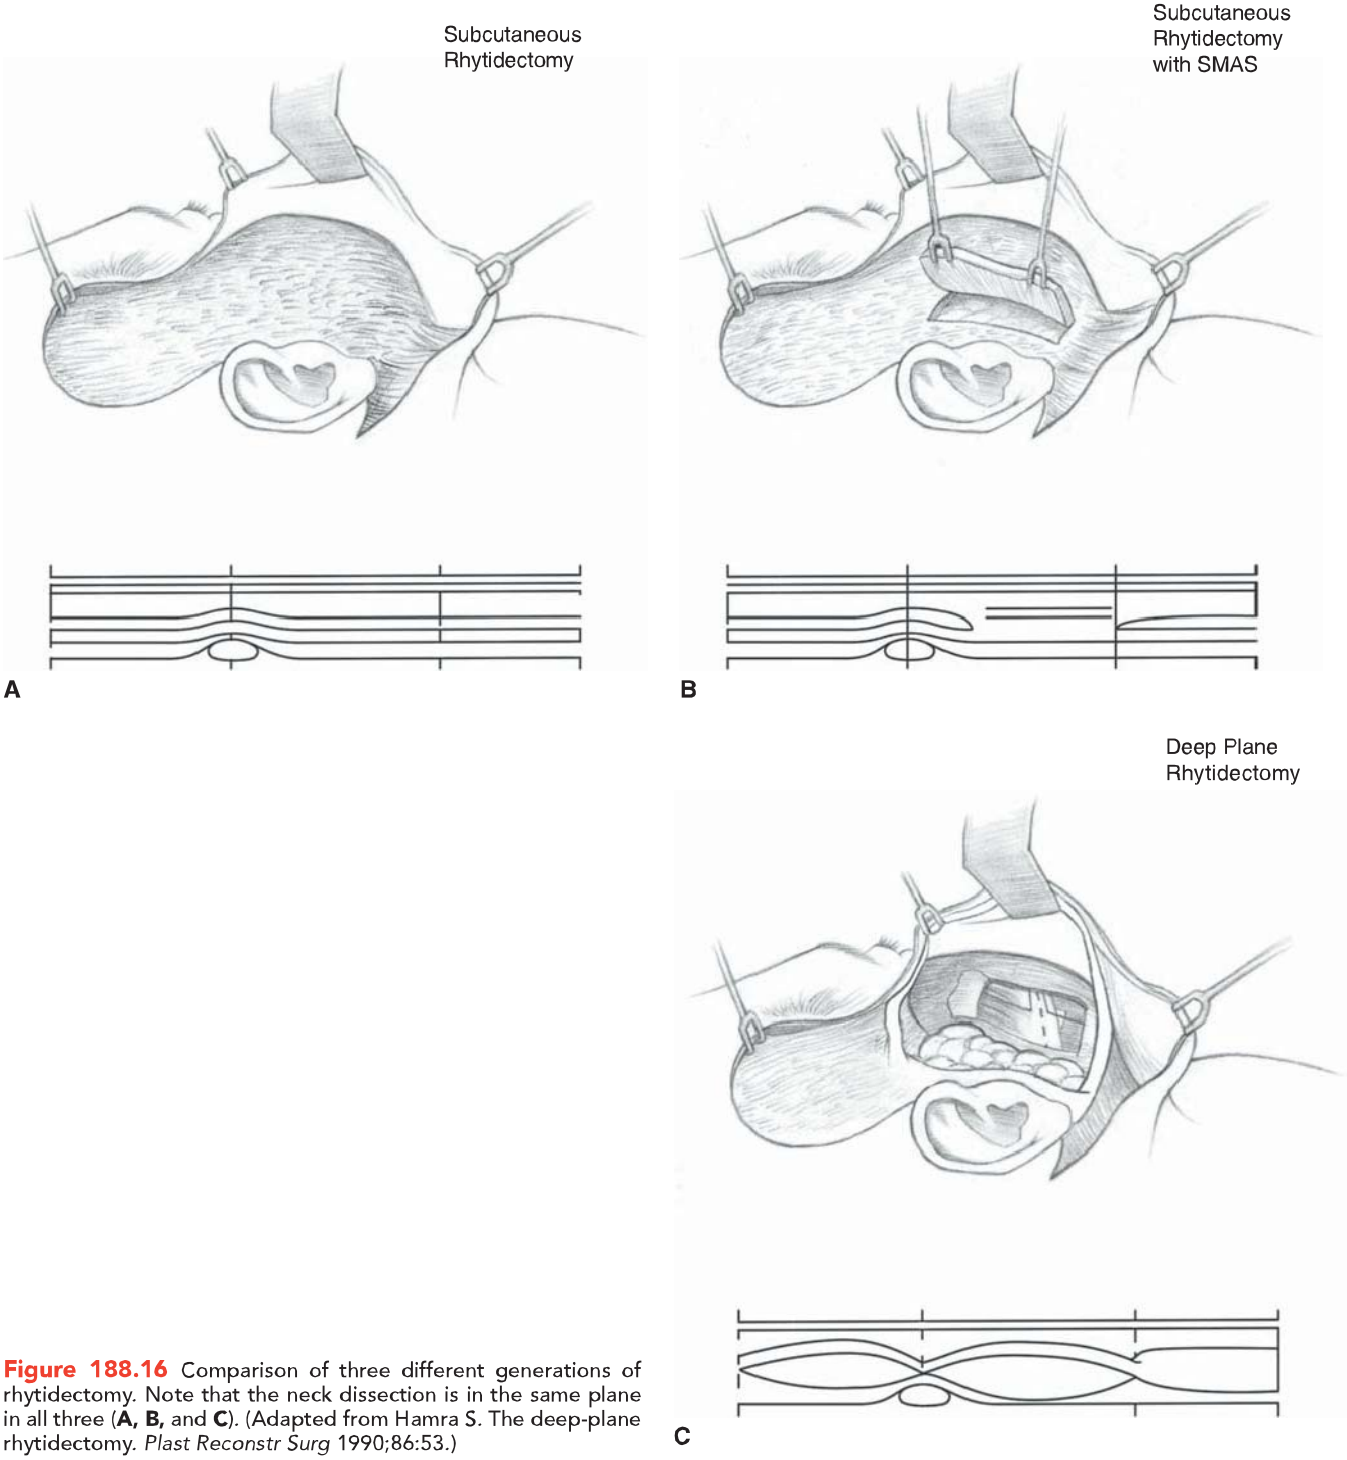

Figure 188.16 Comparison of three different generations of rhytidectomy. Note that the neck dissection is in the same plane in all three (**A, B,** and **C**). (Adapted from Hamra S. The deep-plane rhytidectomy. *Plast Reconstr Surg* 1990;86:53.)

and is connected subcutaneously with the contralateral dissection. A platysmaplasty with submental lipectomy is performed. In this area, the operation is similar to that already described.

Dissection of the lower face is carried out in a sub-SMAS plane, in contradistinction to the subcutaneous plane described previously but similar to most SMAS imbrication techniques. One significant point of difference with established techniques is that the sub-SMAS dissection is carried out anterior to the parotid, where the buccal and marginal branches of the facial nerve may be encountered. A second distinction is that the subcutaneous plane is developed only minimally so that the bulk of the elevated flap contains SMAS along with the skin and subcutaneous fat.

Finally, dissection in the midface is carried out over the malar eminences into the central face. This dissection is much more extensive than in other SMAS suspension techniques. The subcutaneous plane is maintained initially for 2 to 3 cm anterior to the tragus, presumably to avoid injury to the frontal branch of the facial nerve. A thick flap then is developed anteriorly, with dissection immediately superficial to the orbicularis and zygomaticus muscles. No other motor nerve branches should be encountered in this plane, as they enter the muscles from their deep surface (53). The two facial dissection planes are bluntly connected to create a large, thick flap. Excess skin is excised after the flap is resuspended at the SMAS level under tension (25).

The major theoretical advantage of this and similar procedures is that the malar fat and skin can be elevated and resuspended, and the nasolabial fold can be undermined, allowing for its effacement. Additionally, the face-lift flap is maintained as a "myocutaneous" flap (25) consisting of platysma, SMAS, and the superficial tissues, purportedly allowing increased viability and closure under greater tension than is possible with standard procedures. Further possible advantages include a decrease in hematomas because of a more avascular dissection plane and a decrease in skin slough due to the theoretically increased viability. The major theoretical disadvantage of the deep plane dissections is the increased exposure to the facial nerve in the lower face with the concomitant possibility of injury. Moreover, patients with deep rhytids or acne scarring may also find improved results from SMAS suspension with an extended skin flap, which may stretch the skin itself more directly. Because of the widespread interest in this procedure, it is important to evaluate these potential advantages and disadvantages critically.

If ptotic subcutaneous fat in the malar region is a significant contributor to a prominent nasolabial fold, one could predict improvement in the nasolabial fold with infrazygomatic undermining, as described by Hamra and others (24,25,54). This fat is not to be confused with the buccal fat pad (of Bichat), which gives the cheek most of its fullness but lies at a deeper plane, in intimate association with the facial nerve. On the other hand, anatomic studies of the nasolabial fold demonstrate that it usually consists of little more than skin excess (21,55). In this case, it would seem that only skin resection, and not deep tissue repositioning, is capable of attaining significant improvement in this area. Because the current SMAS suspension procedures usually do not involve undermining medial to the malar eminence, the deep plane procedures as described should obtain some advantage in malar skin redraping and resection.

As for theoretically improved viability with the deeper plane of dissection, this depends on the vascular anatomy of the flap. For the deep plane face-lift flap to be a true fasciocutaneous flap of the SMAS based on the facial artery, as asserted, there must be multiple small perforators from the SMAS to the overlying skin, with only the distal few centimeters immediately anterior to the pinna left random, as this area is undermined subcutaneously. At least one recent study of the vascular anatomy of the face calls this interpretation into question (54). The authors observe vast numbers of small perforators from the facial system in the medial face but only sparse perforators in the transverse facial and posterior auricular distributions. Abundant small perforators from the facial system via the SMAS fascia are not described. Indeed, subcutaneous face-lift dissection results in little bleeding above the jawline and in front of the ear, except for the transection of the transverse facial perforators, which are divided in the deep plane dissection as well. These observations suggest the possibility that both the classic and deep plane face-lift flaps are similarly viable large random flaps. As skin slough is a relatively rare complication, extensive experience with deep plane lifting will be required before reliable empiric judgments can be made.

A much lower incidence of hematoma (about 1%) relative to the classic procedure (8%) is reported for the deep plane procedure (25), providing some indirect evidence that the dissection is more avascular. Given that dissection in the neck for both procedures is in a similar plane, only the facial hematoma incidence is likely to be lower. It may be, however, that neck hematomas can be reduced as well by remaining strictly in the preplatysmal plane as recommended by Hamra (25) rather than hugging the subcutaneous tissues as described above, regardless of whether a deep plane or a more standard SMAS suspension procedure is performed.

In most SMAS suspension procedures practiced today, the facial nerve is well protected. As long as SMAS undermining is not carried forward of the anterior margin of the parotid, the nerve is shielded by the gland parenchyma. Anterior to the gland, the nerve courses within the buccal fat pad deep to the SMAS and therefore is exposed to injury by SMAS undermining in this area. In a similar vein, dissection that remains meticulously superficial to the zygomaticus will protect its innervation; however, the branches to the lower orbicularis are more superficial (the orbicularis lies in a plane superficial to the zygomaticus) and may be

vulnerable to injury by dissection over the malar eminence if care is not exercised to remain strictly superficial to the orbicularis as well (53). Both areas are manipulated by the deep plane lifting techniques, which therefore carry theoretically greater risks of nerve injury. A working estimate of the incidence of temporary weakness in deep plane face-lift can be obtained by combining cases from several recent reports (25,56,57). These authors report a total of 23 cases of temporary paralysis in 638 deep plane rhytidectomies, for an estimated incidence of 3.6%. By contrast, a classic review of facial nerve injury in more standard rhytidectomy revealed 50 cases of paralysis in 6,500 rhytidectomies, for an incidence of 0.8%. Seven of these cases were permanent (32). Although no cases of permanent paralysis have yet been reported for deep plane rhytidectomy, it would seem reasonable that the incidence would be correspondingly higher.

Figure 188.17 Pixie-ear or satyr-ear deformity caused by excessive skin excision or tension at the earlobe.

Flap Closure

Drains

Many surgeons elect not to drain their standard face-lift flaps and reserve drains for excessively long procedures or those in which less-than-perfect hemostasis was achieved (58). A successful argument can be made for omitting drains because the percentage of early seroma and hematoma formation is quite low, and no one has been able to demonstrate that either open or closed suction drainage systems prevent hematoma.

The authors nevertheless favor the use of closed suction drainage in our face-lift patients. The authors have noted great improvement in early skin flap adherence to the deeper layers of dissection because the drains actively remove small amounts of fluid. The authors' patients have reported much less discomfort with suction drains than without them, perhaps because there is no fluid pressure buildup beneath the flap. A Blake perforated drain is placed through a separate posterior stab incision. Aspiration via a bulb suction device continues until the first postoperative day, or longer on rare occasions. A fluffy pressure dressing is still used to support the face and neck and ensure uniform, gentle pressure on the flap.

Earlobe and Tragus

Special attention is given to the flap closure about the earlobe and tragus to prevent postoperative sequelae often associated with these structures. An elongated earlobe directly attached to the facial cheek skin, known as the pixie or satyr earlobe, is a common complication (Fig. 188.17). Other problems include earlobes that are too pendulous and scars visible below the earlobe.

Prevention is by far the best management of these difficulties. During closure, a generous amount of perilobular flap skin needs to be left around the earlobe. Additionally, the skin flap may be fixed to the SMAS or mastoid fascia superiorly. The authors have seen consistently pleasing earlobes in our face-lift patients by adhering to the following principles. The earlobe complex is dissected completely free from the skin and subcutaneous tissue, rendering it completely mobile. After the initial perilobular flap cut is made before SMAS plication, the authors seldom alter this incision length (Fig. 188.18). Before closure, the earlobe shape is preserved by a horizontal mattress-type suture of 5-0 Prolene, as described by Clyde Litton (personal communication, Washington DC, 1986) (Fig. 188.19). This suture suspends the earlobe superiorly, maintains a normal crease, and prevents the lobe from being pulled downward. The inferior edge of the earlobe is attached to the skin flap by a separate individual Prolene suture.

The tragus shape and projection are similarly affected by flap-closure techniques when a posttragal incision is used. Common postsurgical tragal deformities include blunting, irregularity, and anteriorly dislocated cartilage. Blunting is prevented with a pretragal deep polydioxanone suture (Figs. 188.20 and 188.21). This suture will help recreate the anatomic pretragal sulcus. Moreover, in addition to defatting the skin overlying the tragus, the flap in this area is trimmed to leave a generous portion of extra skin that more than sufficiently covers the tragal cartilage without tension. This segment is sutured to the canal portion of the tragal skin with individual 5-0 plain gut sutures, taking care to avoid needle entry into the cartilaginous tragus.

Wound Closure

The postauricular flap and the temporal region have been trimmed and the incision approximated in these areas by using skin staples. Wound-edge eversion is helpful to fine-line incision healing. The authors oppose the skin edges with a lightly run, locking suture of 5-0 plain gut, even in areas that have been stapled. This hemostatic-type stitch also ensures an airtight flap closure, which allows the suction drain to function more effectively. This extra attention to wound eversion is worth the effort as it seems to improve the appearance of the incisions.

SPECIAL CONSIDERATIONS

Male Face-Lift

Although men seek facial rejuvenation less commonly than women, the numbers of male face-lifts are increasing. The novice surgeon should be aware of the few differences that exist between male and female face-lifting. Although mostly technical, differences are also on the psychological level. Some authors agree that males seeking rhinoplasty tend to be more detail oriented and demanding than women. However, when it pertains to face-lifting, the authors believe it is quite the opposite phenomenon. Female patients are often very particular about any kind of asymmetry, wrinkle, or bulge that is left or any result that does not return them to the way they were many years ago. Generally, female patients will have better aesthetic results following surgery. This might be due to the fact that men have thicker skin perhaps secondary to beard formation and also have larger parotids that could contribute to a fuller cheek appearance.

From a health perspective, men tend to have more cardiovascular diseases, for instance, making them at an increased surgical risk compared to women of the same age. One should be careful to inquire about past medical and family history to better coordinate patient care with the primary care provider and obtain medical clearance.

The pattern and distribution of facial and temporal hair in a male patient are important preoperative considerations. In a patient with severe temporal recession, in a bald patient or in a patient who shaves his head, counseling is important as incision placement would be apparent despite the greatest effort in planning. Many factors affect incision placement not only in the preauricular area but also around the earlobe and in the postauricular area. Some surgeons prefer a pretragal rather than a posttragal incision in male, for fear of bringing hair-bearing skin over the tragus (Figs. 188.22 and 188.23). This certainly is a concern, especially in patients with lax skin where the surgeon is planning considerable amount of cutaneous resection. In patients that prefer a retrotragal incision, the authors directly address the hair follicles by cutting them with the scissors flat on the undersurface of the flap. Cautery can often assist in this task as well. This is done when thinning the newly formed tragal skin, remaining careful not to be overaggressive to prevent postoperative epidermolysis over the prominent tragal area. Such planning prevents a scar in the preauricular area, but risks the presence of hair on the tragus, in spite of inactivation of the hair follicles. The authors inform patients that they may need postoperative electrolysis or laser hair removal in this region. Because the male sideburn blends into the beard, loss of the temporal tuft is less problematic than in female patients, as the sideburn could be recreated from growing the beard. Therefore, a curving vertical incision in the posttuft scalp rather than anterior to the tuft is permissible in men.

The incision around the earlobe is generally at the inferior attachment, except in male patients where a margin of non–hair-bearing skin is preserved so hair does not abut the lobe postoperatively, bringing discomfort to the patient and added challenge when shaving in that area.

The third area that needs additional planning is the postauricular incision that extends over the mastoid and the occipital hair. This incision generally is drawn over the posterior surface of the concha before continuing in the hair in female patients. In men, it is preferable to place it lower, at the level of the cephaloauricular groove. This will prevent hair-bearing skin from reaching the concha, making shaving again an awkward task. However, the authors still inform male patients the need to shave over a new zone in the postauricular area as the hair-bearing skin flap is relocated posteriorly and superiorly.

During skin flap elevation over the cheek and the neck, one should be careful not to create too thin of a flap in males. This might inadvertently injure the hair follicles and create areas of permanent patchy beard alopecia. Skin flap thickness should be examined both from outside and from under the flap throughout the dissection to allow evenness and safe movements. Ideal skin thickness is achieved when the surgeon can see the untraumatized hair follicles from under the flap. In that regard in males, the thickness of the flap can vary from patient to patient, and it is often dictated by the depth of the hair follicles.

Last but not least, increased rates of postoperative hematoma have been reported in male patients, perhaps due to the rich subdermal plexus feeding the hair follicles.

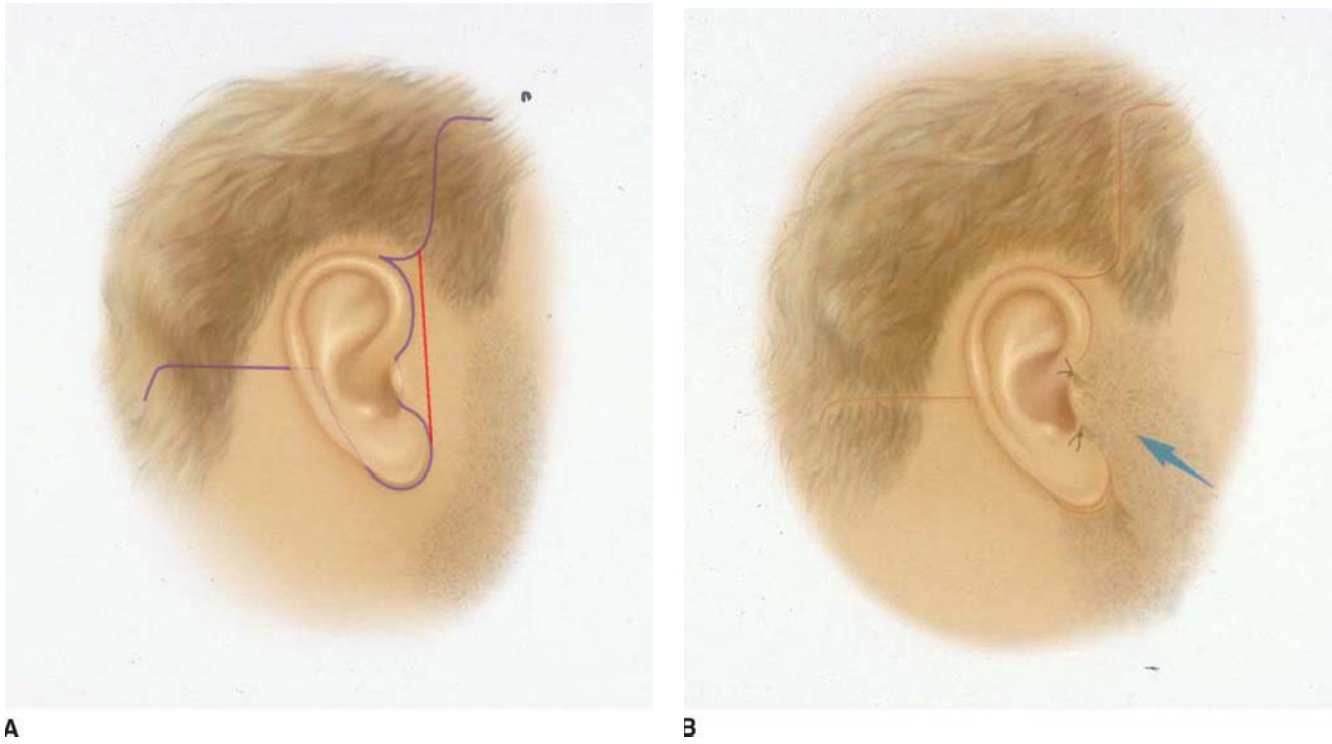

Figure 188.22 **A:** Schema of two options for male face-lift incision. Note a cuff of non–hair-bearing skin is left around the lobule, and the postauricular incision is placed in the sulcus and not onto the concha, as in women, to prevent men from having to shave in these areas. **B:** Schema of the retrotragal male incision after skin excision and flap redraping. The tragus is now covered with hair-bearing skin. Note also the preserved non–hair-bearing cuff of skin around the lobule. (Reprinted from Kridel RWH. Techniques for inconspicuous face lift scars. *Arch Facial Plast Surg* 2003;5:323–333, with permission.)

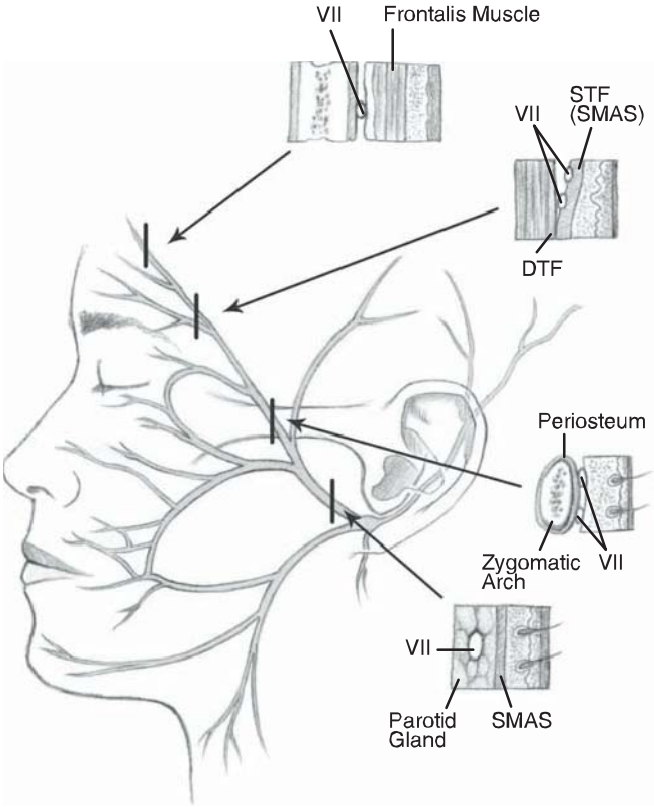

Figure 188.23 The frontal branch of the facial nerve at different locations in its course.

Some surgeons prefer the deep plane lift, advocating a lessened risk of hematoma formation as the ramified subdermal plexus is left intact.

Secondary and Revision Face-Lift

Despite our best intentions, plans, and efforts, some patients may be unhappy because of real or perceived unsatisfactory results. Remember that the patient may not always be as critical of the outcome as the surgeon. The authors consider it inappropriate to impose our desires for near perfection on a patient who otherwise may be perfectly happy with the degree of improvement. On the other hand, mutual concerns over acquired asymmetries, incomplete lifts, persistent facial irregularities, or general unsatisfactory results are best acknowledged openly, with plans made for further correction if possible. Of course, face-lift surgery does not arrest the aging process, and the need for minor tuck-up procedures should not be considered a complication of face-lift surgery. This is especially true in older patients whose skin has lost its elasticity and heavy neck patients who require a lot of fat removal. In fact, some surgeons believe in planned, sequential rhytidectomy and address this issue in the preoperative assessment (36,63). Other than being indicated for recurrence of the signs of aging in the lower two-thirds of the face and neck, a revision or a tuck-up might be indicated when a previous procedure was underdone or overdone or when

complications have arisen during the postoperative course. A partial revision could thus be planned to specifically address localized problems. Just as with primary surgery, secondary surgery could be tailored to address one or more specific areas. For instance, a recurrence of platysmal bands in the neck can be corrected with a platysmaplasty alone without having to do a full face-lift. Other indications for secondary surgery include persistent or recurrent jowling, platysmal bands, submental fat, or lax skin.

A prior face-lift or other neck surgery may complicate the proposed procedure. The placement and quality of prior face-lift incisions should be noted and discussed with the patient. Although it may be desirable to revise scars at the time of surgery, the surgeon might not be able to resect the entire width of a scar, specifically when the scar is wider than what could be excised without risking a tension closure after redraping the skin. Closing under tension would risk the same complication one is trying to correct.

Additionally, it may be useful to explore the patient's attitude toward the prior surgery. If the patient was dissatisfied with the result, the surgeon should proceed with caution and further evaluate the patient's motivations. The patient may have been reasonably unhappy with a poor result, but he/she may also be difficult to please, even with a technically sound job.

Dissection might technically be more difficult in a secondary surgery due to previous scarring in the deep tissues. Furthermore, scarring could have incorporated branches of the facial nerve especially if the SMAS has been elevated, rendering dissection more dangerous. If the SMAS was previously addressed with plication, that same technique could be safely utilized again for the revision, as one will not be in a sub-SMAS plane. Nevertheless, plicating the SMAS might still be a challenge as it has possibly been weakened. Sutures might just tear through thinned tissue and desired tension will have to be achieved with the use of an increased number of stitches. Some surgeons have reported that particularly in these revision cases a deep plane lift sometimes allows for better planes of dissection. The surgeon must be honest with himself or herself and with the patient about his or her ability to improve the aesthetic result. Any other prior neck surgery or irradiation might also adversely affect the ease of dissection and progress of healing or, as in the case of neck dissection, might expose deep neck structures to catastrophic injury. Incorporating these considerations into the surgical plan will help avoid a grave outcome.

POSTOPERATIVE CARE

The patient should be given detailed typewritten postoperative instructions before the surgery to allow the patient and his or her family to read the instructions in detail and ask questions before surgery. After surgery, the patient and family are informed again of problems that might arise and instructed to call the physician for any questions.

The authors use a large bulky dressing right after surgery, partly to discourage turning of the head, which can lead to hematoma formation. Patients often complain that their bandage is too tight right after surgery, which usually indicates that they are feeling the tightening of the lift and the bandage. If a compressive dressing is used, the surgeon can make a vertical incision in the midline of the dressing at the inferior border and see if there is any relief, but patients must be ready to accept a feeling of tightness.

Postoperative orders are geared toward keeping the patient calm and as pain-free as possible. Increased pain leads to increased blood pressure, which can increase the likelihood of complications. Likewise, a full bladder after a long procedure can increase blood pressure.

The surgeon should check on the patient the night of surgery. Any unilateral pain that is unrelenting and unresponsive to routine pain medication should alert the physician to possible hematoma formation and must be addressed as soon as possible. The patient also should be seen on the first postoperative day; drains are usually removed at this time, depending on the amount of drainage noted. Before releasing the tension of the bandage and removing the drains, fluffs are held over the area from which the drains are going to be removed, and pressure is applied. Pressure is maintained in those areas until a new bandage can be reapplied. This step helps to keep down the flaps and prevent hematoma or seroma formation. Before placing the new dressing on the first postoperative day, antibiotic ointment or cream is applied on all incisions (we prefer gentamicin cream), making sure to apply some at the external auditory canal to prevent any *Pseudomonas* from the external canal from contaminating the incisions.

Usually by the second or third postoperative day, the large bulky dressing can be totally removed, and an elasticized facial sling can be used. This helps the skin flap to maintain close contact with the subcutaneous tissue and provides faster revascularization and even contraction. It is important to pad the ears because these elasticized bandages can rub the thin skin of the pinna and thus cause irritation.

Usually on the fifth postoperative day, a few of the anterior preauricular stitches are removed, and the patient's hair is washed in a shampoo sink in the office. Patients are cautioned not to use hair dryers in the immediate postoperative period because some numbness of the periauricular and scalp areas will be present, possibly causing patients to burn their skin with the hair dryer due to lack of sensation.

Over ensuing visits, all the sutures are removed and the incisions examined under the microscope, especially in the hair-bearing areas to check for ingrown hairs, which can occur up to several months after surgery. After performing beveled incisions, this step also ensures that the hair will actually grow through the incision for camouflage. Often hairs become trapped and need help to come through the advanced flap.

Almost all patients have significant swelling or bruising postoperatively, and often this is difficult for the patient to accept. Gentle reassurance is key in the first postoperative weeks. As Goin and Goin (59) pointed out, if everything has gone well and the results are good, it is important for the physician to tell the patient so. Patients do not know how they should look and whether things were done well unless the doctor says so. Patients often forget what they looked like before surgery. For that reason, giving them prints of their preoperative photographs at the first or second postoperative visit is extremely helpful. This allows patients to compare their preoperative and postoperative conditions.

COMPLICATIONS

Nerve Injury

Injury to the facial nerve is fortunately a rare complication, with a reported incidence of between 0.4% and 2.6% (35,60–62). The motor nerve branch most vulnerable to direct, technical injury is the frontal branch of the zygomatic–temporal division of the facial nerve. This is because of its superficial location as it traverses the midportion of the zygomatic arch (Fig. 188.23). The authors avoid deep plane dissection entirely in the region superior to the arch and anterior to the temporal hairline to negate the risk of frontal nerve branch injury. Anatomic considerations are important for the marginal mandibular nerve and buccal nerve divisions as well. Marginal nerve injury results in an asymmetrically oriented smile with a higher position of the lower lip on the affected side due to unopposed action of the opposite depressor lip musculature (Fig. 188.24). Platysma transection and excessive SMAS traction in the region near the angle of the mandible and inferior mandibular border can result in marginal nerve paralysis. Buccal motor nerve branches are injured with aggressive dissection medial to the anterior border of the parotid gland. An asymmetric flattening of the midfacial contour may accompany buccal division injury.

Total facial nerve injury is extremely rare. If it is seen postoperatively and complete nerve transection is doubtful, consider a concomitant Bell's palsy (60). Transient paralysis of one or more facial nerve branches often is related to local action imposed by infiltrative anesthesia. Any prolonged paresis merits additional investigation and should not be attributed to the lidocaine effect. Additional causes of facial nerve injury include thermal injury by electrocoagulation; crush or pinch injuries caused by instrumentation or deep suture ligature; excessive SMAS traction; inflammation or infection; pressure from hematoma formation; and distortion, fibrosis, and scarring from previous face-lift surgery (60).

The most commonly injured nerve is the sensory greater auricular nerve because of its intimate association with the firm fascia surrounding the sternocleidomastoid muscle (62,63). Another nerve that is often overlooked both in the literature and clinically is the lesser occipital nerve. Although variable in its innervation pattern, Pantaloni found that in more than half of the cases, it innervated the superior third of the auricle and the mastoid area. And in 21% of patients, it innervated the upper two-thirds of the ear. Also, rarely (in about 5%) it will innervate the majority of the ear (64). Often, the skin flap is adherent in the area of both nerves and sharp dissection or traction can injure the nerve, resulting in permanent sensory deficit of the ear and periauricular skin. Meticulous precautions are paramount in that region.

Hematoma

With a reported incidence as high as 8.5%, hematoma formation remains the most common and feared complication of face-lift surgery (58,60,63). Expanding hematomas require immediate reoperation to control the bleeding source and to evacuate and drain the newly dissected skin flaps. Rapid filling of a suction drain reservoir is a sign of bleeding that must be investigated. Fortunately expanding hematomas are less frequent than small collections. Smaller or delayed hematomas can be managed with serial needle aspiration and pressure dressings. Patient complaints of pain, swelling, or firmness of the buccal region and ecchymosis, especially if unilateral, necessitate immediate inspection of the skin flaps. Intraoral inspection revealing mucosal ecchymosis often signals a hematoma that may be hidden by the external bandage.

Techniques that seem to reduce the incidence of hematoma formation include careful attention to intraoperative hemostasis, closed suction drainage, shorter skin flaps, and two-layer or deep plane face-lift technique. Unrecognized and improperly treated, hematomas result in skin necrosis, infection, prolonged ecchymosis, alopecia, subcutaneous nodules and skin puckering, and scar contracture.

Different factors can help decrease hematoma formation in the postoperative period. Some were already discussed earlier but are reiterated herein and cannot be overemphasized enough. First of all, coordination with the anesthesiologist is crucial for a smooth awakening. Coughing on the endotracheal tube will directly increase the blood pressure and potential bleeding under the flaps. Also, adequate blood pressure control both in the operating room and the postoperative period, especially in patients with a history of increased blood pressure, is paramount. Analgesia and antiemetics help reduce the pain and prevent nausea and vomiting, factors that can otherwise contribute in elevating the blood pressure. Making these medications readily available for the patient in the immediate postoperative period is crucial. Some surgeons have advocated prescribing these medications to be taken regularly rather than on a *pro re nata* regimen, minimizing any potential delays from nursing. Patients are also asked to refrain from exercise as this too can augment the

pressure. Compressive dressings, use of drains, and tissue sealants are also advocated by many surgeons.

Incision Problems

Tension on the suture line and skin flaps is the key danger to any face-lift procedure that otherwise may have been executed flawlessly. Careful preparation, incision placement, SMAS suspension, and accurate skin flap redraping without tension minimize incision complications. Preventing tension on skin incisions is the best way to avoid unattractive wide scars, skin slough, and hypertrophic scarring.

Cyanotic changes precede skin necrosis but sometimes can be reversed by increasing the oxygen tension to the skin flap. Often removing a few key sutures is helpful in releasing tension. A skin gap may granulate in if skin slough occurs, spontaneous demarcation with expectant management may limit the extent of tissue loss (65). Superficial debridement and topical antibiotic ointment can clean the wound and begin the process of reepithelialization. Keeping the wound bed moist and avoiding dry and crusted surface have been shown to significantly accelerate reepithelialization.

Active, hypertrophic scars respond to serial injections of triamcinolone at 3- to 4-week intervals. Silastic or silicone sheeting may also prove useful along with scar massaging. Direct excision of residual hypertrophic scars or widened incisions is delayed until after the inflammatory phase, when considerable skin relaxation and healing have occurred. In rare exceptions, one could earlier revise a scar that has obvious and significant deformity with little hope to improvement.

Prevention of structural deformities such as the satyr earlobe or pixie ear, blunted and anteriorly dislocated tragus, elevated temporal hairline, and conspicuous incisions such as suture tracking and posterior hairline step-off has already been thoroughly discussed. Chondritis of the tragus, external auditory canal, and auricle are reported in the literature and may result in structural deformity. Suspected chondritis often responds to ciprofloxacin or other antipseudomonal and antistaphylococcal antibiotics. Undesirable creation of a bloody culture media in the ear canal can be avoided by occluding the canal before surgery with an iodine-soaked cotton ball. Also, no sutures are placed through tragal cartilage, thereby preventing the direct introduction of organisms to the cartilage.

Other incision problems include ingrown hairs, which can establish a nidus of infection and inflammation. During each postoperative visit, ingrown hairs are identified by magnified inspection of the incision and removed. Occasionally, buried permanent sutures used in SMAS suspension find their way to the skin surface. Removing sutures that have extruded after a long follow-up should create no difficulty for the patient. Rarely, persistent hemosiderin deposits are visible beneath the skin and require cosmetic cover.

Alopecia

Other than poorly planned incisions, tension seems to be the main cause of postoperative alopecia. Some loss may be transient and results from temporary surgical stress to the hair follicles during the perioperative period. This phenomenon, better known as telogen effluvium, affects normal hair around the incision sites. These hair follicles do not undergo physical transection from the surgical knife, and hence, patients should be counseled that hair is expected to grow back within 3 months. Many series report an incidence ranging from 0.2% to 1.8% (58).

In contrast, when scars develop, they are usually more noticeable because of the permanent alopecia that accompanies the scar formation. When that is the case, single–follicular unit hair transplantation can be achieved. In males specifically, the donor source should be from an area of the scalp that is not expected to undergo androgenic alopecia with time. This is typically the occipital area. However, if one is planning a revision face-lift with skin resection, follicles from resected scalp in the postauricular area while redraping could be used as a potential transplant source, obviating the need for a separate occipital incision. The small number of follicles harvested from that technique might be a limiting factor if the coverage needed at the recipient site is substantial. It is interesting to note that hair shafts harvested from the lateral occipital regions tend to be thinner. That often is an advantage when reconstructing the temporal hair tuft where shafts are also of a more narrow dimension (Fig. 188.25). Other than hair transplantation, one could rely on excision of the area of alopecia with tissue advancement. Larger areas of alopecia may also require tissue expansion with hair flap rearrangement for aesthetic, full-density hair coverage.

Final Word

The dictum "above all else, do no harm" is of paramount importance in elective aesthetic facial surgery and should be heard loudly in every surgeon's ear while planning and performing facial rejuvenation surgery. Functional, permanent, or disfiguring complications can be particularly devastating to patients who were not ill but simply wanted to look and feel better about themselves. Honesty and integrity must characterize the relationship between the surgeon and patient, and patient education is important to that relationship.

The deep plane techniques have led surgeons to think more rigorously about facial anatomy and the goals of rhytidectomy. Many of these techniques ultimately may be incorporated into standard rhytidectomy practice. Until that time, however, continued critical assessment of the benefits and risks of these procedures is needed, and caution is urged for surgeons contemplating deep dissection in the medial face.

HIGHLIGHTS

- The ideal patient for face-lift surgery is aged in the mid-40s to mid-50s and in good general health; has a strong jawline, chin, and cheekbone; and has a high posterior hyoid, a relatively thin neck and face, and minimal photoaging of the skin.
- Rhytidectomy mainly corrects ptosis of the jowl and blunting of the cervicomental angle. If creases and wrinkles of the skin contribute to the aged appearance, one should consider chemexfoliation or laser resurfacing as an adjunct procedure. Periorbital and perioral resurfacing can be done safely at the same sitting as rhytidectomy.
- The "face-lift" is truly only a cheek and neck lift, and often ptosis of other facial regions also contributes to the aged appearance. Achieving facial harmony between different regions will provide natural non-operated results. Thus, blepharoplasty, forehead lift, and other rejuvenation surgery should be considered at the same sitting as the face-lift. Final face-lift results depend on a good, strong bony framework; augmentation of the cheekbones, submalar areas, and chin also may be necessary.
- To assess whether a patient's expectations are realistic, ensure that improvement and not perfection is the mutual goal, that the patient does not expect to look exactly as she or he did many years ago, and that the patient understands that a face-lift is surgery, with inherent risks and possible complications.
- Thorough preoperative evaluation of the patient's medical condition is mandatory. Because smoking

greatly increases the risk of skin slough, smokers should be operated upon cautiously. Medical conditions that predispose to abnormal bleeding (e.g., coagulopathies, severe hypertension, hepatic or renal disease), if not correctable preoperatively, are contraindications to rhytidectomy. Coordination with the primary care provider is crucial especially in patients with comorbidities that need medical clearance prior to surgery.

- Incisions must be planned differently for men and women. Preserving the anterior hair tuft is key in women. In men, a preauricular incision is preferable, with maintenance of a hair-free border around the ear and under the lobule to prevent beard hair from annoying the patient postoperatively. Furthermore, in males care must be used to preserve the hair follicles during subcutaneous dissection, avoiding beard alopecia.
- In a SMAS suspension rhytidectomy, the pull should be mainly superior, with only a slight posterior vector to counter the chronic effects of gravity. All tension should be carried by this layer with the skin closed under no tension at all. Too much skin tension can lead to skin slough, increased telangiectasias, or a widened scar. Aggressive cutaneous tension can also lead to an unnatural appearance.
- The debate between SMAS suspension rhytidectomy versus deep plane rhytidectomy on routine patients is ongoing. More objective data will be needed to evaluate the effect and longevity of both techniques on different areas of the face.
- Prominent nasolabial folds are a source of concern for patients and surgeons alike, and improvement with standard rhytidectomy is limited. Deep plane rhytidectomy offers some promise as a means of improving this area, but the cosmetic benefit has not yet been clearly established, and the theoretical risk of injury to the facial nerve is greater than with standard techniques. Caution is urged for surgeons contemplating deep plane approaches to the medial face.
- Theories stressing volume loss and tissue atrophy rather than just gravitational changes have shifted some surgeons toward facial fillers, facial implants, and soft tissue augmentation. These techniques are being used alone and in conjunction with traditional lifting procedures. However, surgical lifts will always have a role in resuspending ptotic tissue.
- Submental liposuction and platysmaplasty have enhanced the degree and duration of improvement in submental contour over SMAS plication rhytidectomy alone. These techniques are routinely used along with face-lift and can be tailored to the patient need and age.
- Secondary face-lift surgery is indicated both for recurrence of the signs of aging and for correcting previously obtained results. Planning incision placement is often more challenging in these cases. Dissection can be more tedious and the risk for facial nerve injury higher with SMAS elevation.
- Hematoma is the most common complication of rhytidectomy and is most likely to occur in the first 24 hours after surgery. Vigilance for symptoms and signs of impending problems is mandatory; quality nursing care to prevent postoperative hypertension is essential. Precise postoperative medications and patient adherence to instructions also help to prevent hematoma formation. Meticulous long-term follow-up care will help ensure an optimal result.

The Aging Neck

189

Edwin Francis Williams *Henry Haipei Chen*

The typical appearance of the aging neck is caused by a constellation of changes associated with both heredity and the aging process. Each patient will demonstrate different anatomic components contributing to the overall appearance of an aging neckline. The anatomic factors that contribute to an ideal cervical contour include a strong chin, a distinct mandibular border, a cervicomental angle of 105 to 120 degrees, a visible subhyoid bone depression, a gentle indentation at the thyroid notch, and visible anterior borders of the sternocleidomastoid muscles (1) (Fig. 189.1). Obtaining these ideal contours should be the goal of any surgical correction of the aging neck. To achieve these goals, however, the surgeon must carefully and systematically analyze each patient to determine the anatomic abnormalities that need to be addressed. An individualized approach ensures that specific deformities are clearly delineated so a youthful and graceful neckline may be restored.

ANATOMY

The aging process exerts an impact on each anatomic element of the cervical region to varying degrees in each patient. Additionally, some patients also display hereditary abnormalities contributing to an unfavorable cervical contour, including a low-positioned hyoid bone, poor chin projection, and a congenital collection of submental fat. Each element of the contributing anatomy should be identified preoperatively and sequentially addressed in the surgical correction to provide an optimal aesthetic outcome. The anatomic areas to be addressed include skin, fat, platysma muscle, chin position, and other unfavorable anatomy (2).

Skin

With time, collagen and elastin fibers degenerate so the overlying skin loses its tone and no longer adheres to the soft tissue contours of the neck. The skin becomes redundant and sags, leading to the development of horizontal cervical rhytids and effacement of the cervicomental angle.

Fat

Fat deposition in the neck can be congenital or acquired. Several anatomic studies have shown that the fat in the submental region is found in discrete compartments (3,4). These areas include (a) a supraplatysmal (subcutaneous) layer diffusely distributed throughout the cervical region, (b) a subplatysmal compartment that overlies the mylohyoid muscle, and (c) facial fat from the cheek and inferior buccal fat pad contributing to a ptotic jowl and loss of the definition of the inferior mandibular border (Fig. 189.2). The subplatysmal layer is further divided into a central compartment between the anterior bellies of the digastric muscles and paired medial and lateral compartments.

Clinically, it is difficult to discern the exact anatomic compartment(s) of submental lipodystrophy, especially in heavy necks. While the use of ultrasonography can be helpful to delineate the areas of excess fat (5), its use is certainly not required as a part of a routine preoperative workup.

Platysma Muscle

The platysma is a paired muscle that is innervated by the cervical branch of the seventh cranial nerve. It originates from the fascia of the pectoralis major and deltoid muscles and ascends in the neck to insert on the inferior border of the mandible (Fig. 189.3). Laterally, the posterior border of the platysma muscle ends in front of the sternocleidomastoid muscle. As the platysma muscle is followed superiorly to the mandible, the medial fibers insert into the periosteum to stabilize one end of the muscle during contraction. The central fibers blend intimately with the risorius muscle. The posterior third of the platysma muscle

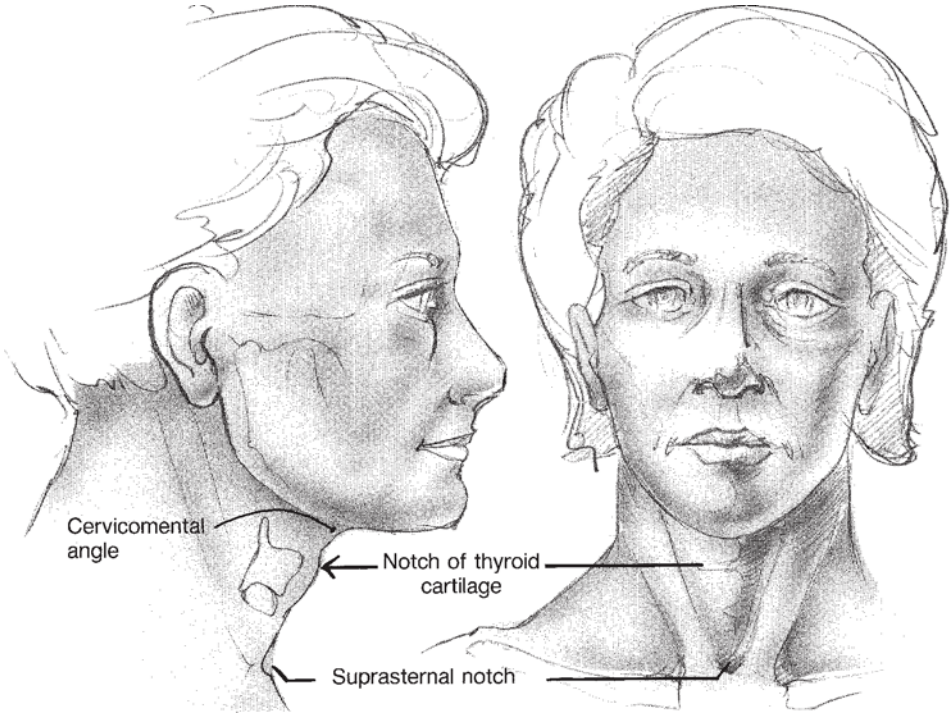

Figure 189.1 The anatomic factors that contribute to an ideal cervical contour include a strong chin, a distinct mandibular border, a cervicomental angle of 90 degrees, a visible subhyoid bone depression, a gentle indentation at the thyroid notch, and visible anterior borders of the sternocleidomastoid muscles.

sweeps up over the mandible to course anteriorly and fuse with the superficial musculoaponeurotic system (SMAS). The cervical skin receives part of its blood supply from perforating vessels arising from the platysma muscle. These vessels and thick fibrous septa coursing through the subcutaneous fat anchor the dermis to the superficial cervical fascia and platysma muscle.

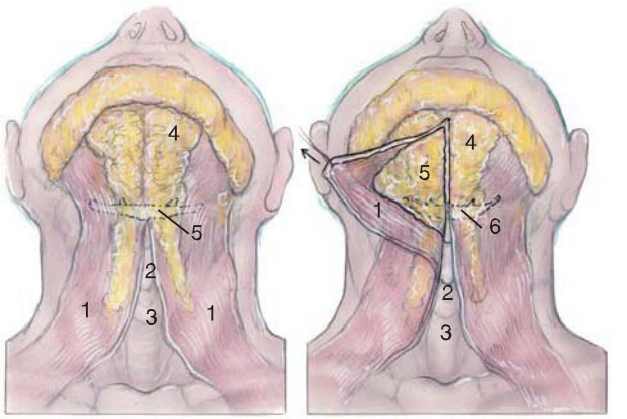

Figure 189.2 Fat is found both superficial and deep to the platysma.

Different degrees of decussation in the midline of the neck have been documented in anatomic studies, and there is also ethnic variability (6,7). The "turkey gobbler" deformity is caused by a laxity in the platysma muscle that does not decussate in the midline.

The platysma muscle functions to stabilize the chest muscles against the jaw during heavy lifting. It also provides a layer over vital structures of the neck. It is a somewhat vestigial structure in humans, corresponding phylogenetically to the panniculus carnosus muscle that forms a continuous subcutaneous layer in lower mammals (8).

With aging, the platysma muscle becomes atrophic and falls toward the midline. First, convexity occurs in the submental region; then, as the muscle loses tone, it forms the pathognomonic anterior banding of the aged neck. On profile, the apex of the cervicomental angle is blunted by the anterior border of the muscle as it runs diagonally from the mandible to the lower neck. Loss of the platysmal muscle sling also allows ptosis of the underlying cervical contents.

Chin Position

An appropriately projected chin is prerequisite for an optimal aesthetic cervical contour. A poorly projected chin creates an illusion of blunting of the cervicomental angle, and aging contour deformities tend to be worse in patients with smaller mandibles and chins (9,10).

Ideally, in a patient with Angle class I occlusion, the pogonion (the most anterior projecting point of the chin) should touch a line dropped vertically from the vermillion border of the lower lip on profile view. It is aesthetically acceptable in women if the chin is slightly posterior to this

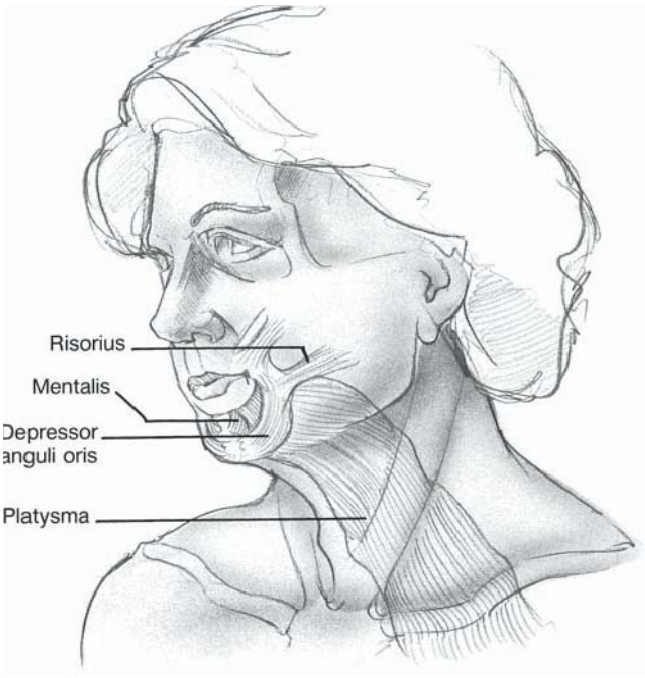

Figure 189.3 The platysma muscle ascends in the neck to blend with the SMAS.

line; however, in men, this line should be tangent to the pogonion (11) (Fig. 189.4). The chin contour is determined by the shape and position of the mandible as well as the overlying soft tissues. A weak chin, or microgenia, is most commonly congenital; however, senile absorption of alveolar bone should also be considered in the older patient.

Mandibular hypoplasia is an acquired condition secondary to varying degrees of bony resorption of the mandible. With aging, specific progressive soft tissue atrophy and bone reduction occur in the region between the chin and jowl. This resulting groove has been termed the "prejowl sulcus" (11). Mandibular hypoplasia should not be confused with retrognathia. Patients with retrognathia demonstrate Angle class II occlusion and are optimally treated with a bony advancement technique (e.g., sagittal-split osteotomy), whereas patients with microgenia or mandibular hypoplasia are better treated with alloplastic augmentation.

Unfavorable Anatomy

The hyoid bone supports the floor of the mouth as it is suspended by the digastric, mylohyoid, stylohyoid, and tongue musculature. Ideally, it should be at the level of the third or fourth cervical vertebrae (12). A more posterior and superior hyoid produces a more aesthetic cervical contour. A hyoid bone that is in a relatively inferior position in the neck causes the suprahyoid musculature to course in a more vertical direction, blunting the angle between the chin and neck (13). With advancing age, gravity may favor the drag of the infrahyoid musculature over the suprahyoid

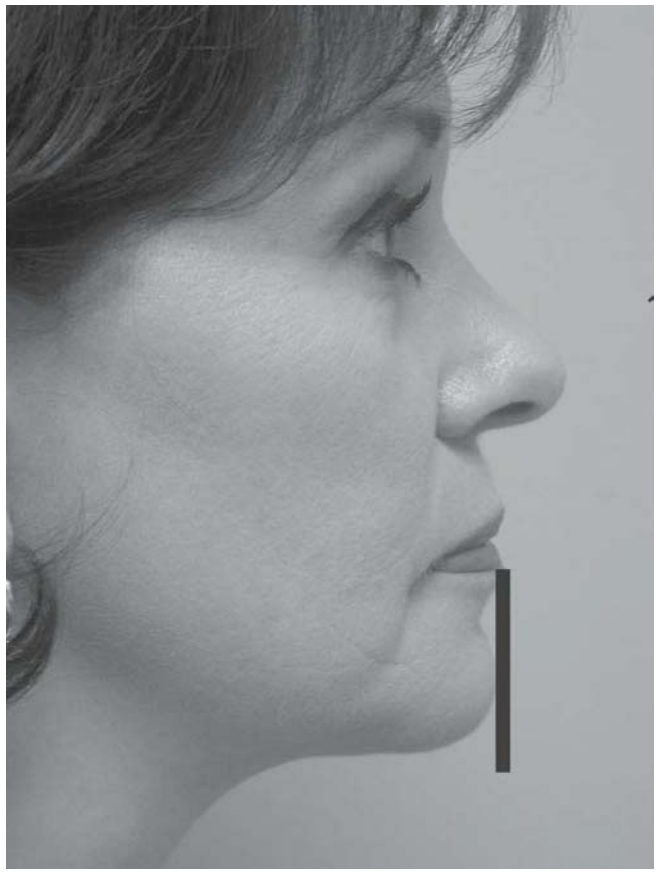

Figure 189.4 The anteriormost projection of the chin (pogonion) should touch a line dropped vertically from the vermillion border of the lower lip on profile view.

musculature, inducing further descent of the hyoid (12). A low hyoid bone position is a major limiting factor in the optimal rejuvenation of the cervical region.

Submandibular gland ptosis is commonly seen with aging, which is identified as two bulges at the anterior edge of the submandibular triangle. Diagnosis is confirmed by palpation of the gland's cobblestoned surface. The position of the glands should be elucidated preoperatively for both patient counseling and surgical planning.

Overdevelopment of the suprahyoid bone musculature, especially the digastric muscles, can also lead to fullness of the submental region. Identification is facilitated by having the patient flex the neck with the mouth closed (2).

CLASSIFICATION AND EVALUATION

Numerous classification schemes describing the aging neck exist (2,14,15). Dedo's (14) preoperative classification of the neck is the most commonly used. It is a useful tool to help delineate the features contributing to a particular patient's pathology and to help guide targeted surgical intervention (Fig. 189.5).

A patient with a class I neck is typically a younger patient who has minimal, if any, deformity, which may or may not require surgical intervention. A patient with a

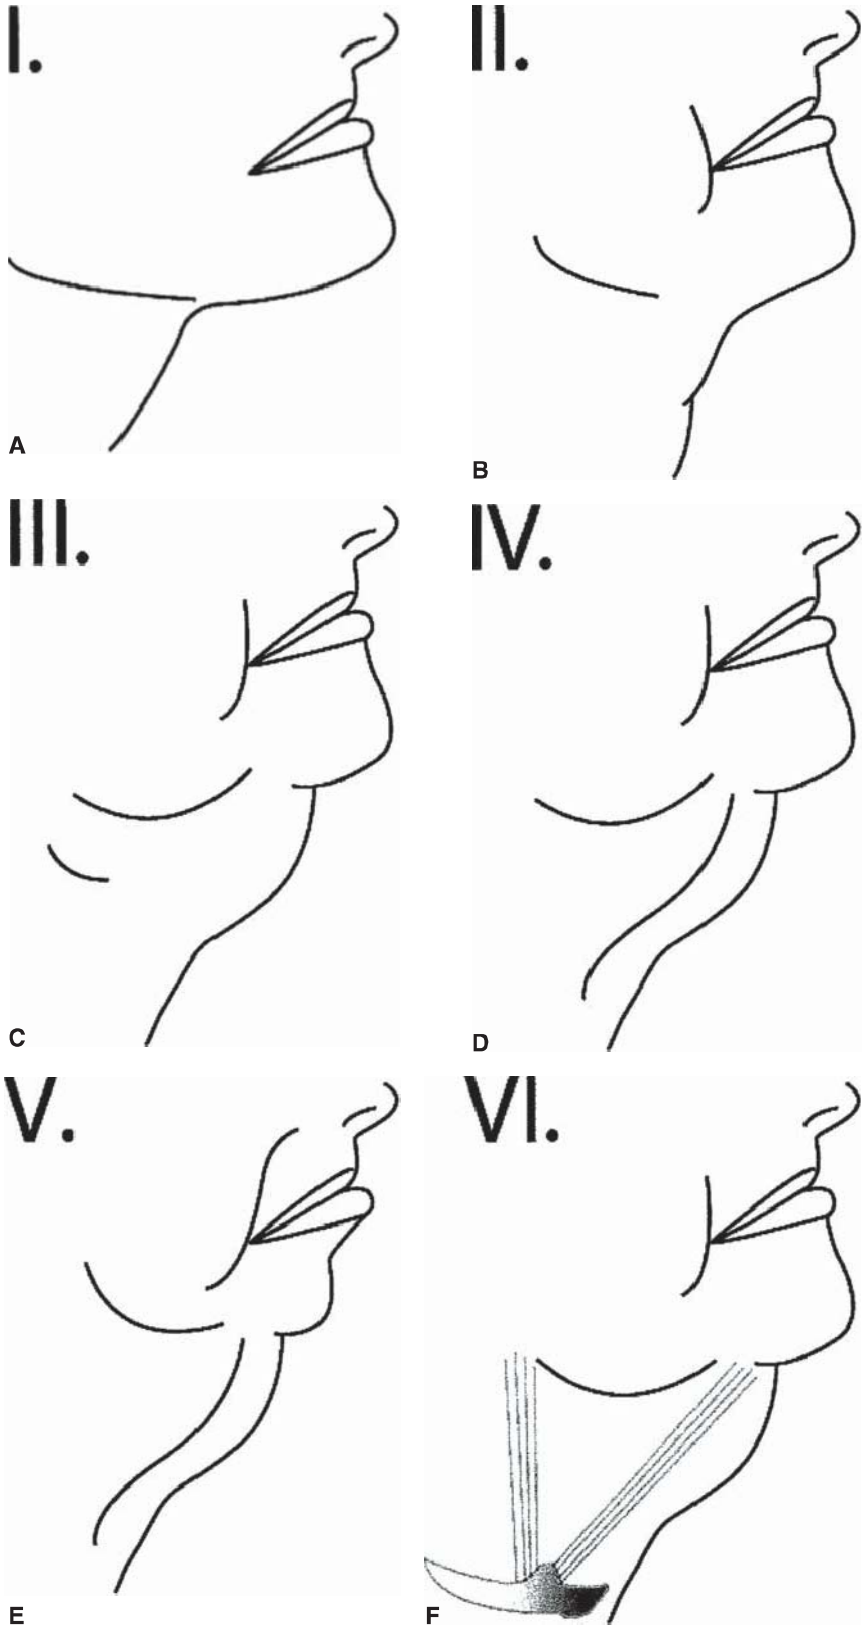

Figure 189.5 Dedo classification of cervical abnormalities: **A:** Class I deformity describes only minimal cosmetic deformity. **B:** Class II deformity describes only skin laxity. **C:** Class III deformity refers to the excessive submandibular and submental adipose. **D:** Class IV deformity refers to anterior banding of the platysma. **E:** Class V deformity describes the condition of microgenia or retrognathia. **F:** Class VI deformity describes a low-positioned hyoid bone.

class I neck should ideally wait until more of an aesthetic problem develops, because any intervention at this time is essentially prophylactic.

The class II patient has skin laxity only, without significant fat or muscle pathology. The class includes the "turkey gobbler" deformity often seen in elderly males.

A class III deformity is caused by excessive cervical liposis. Excess adipose can accumulate in the supra- or subplatysmal layer. Both contribute to jowling.

The class IV patient has a pathologic platysma muscle either in repose or on voluntary contraction. This is usually diagnosed in the thin neck as anterior platysmal banding; however, in patients with submental adiposity or redundant anterior cervical skin, it is often not readily apparent that the platysma muscle is contributing to the deformity. In fact, the full neck does not evidence platysmal banding, even with aging (3). In this case, diagnosis is facilitated by having the patient grimace with the teeth clenched to delineate the medial and lateral borders of the muscle (Fig. 189.6).

The class V patient has a weak mandibular projection from congenital or acquired causes. Although the terms retrognathia and microgenia have been used interchangeably in the scientific literature, each word denotes a different condition. The term microgenia, referring to an underprojected chin, independent of occlusal consideration, is more appropriate to describe most of these patients. Retrognathia, on the other hand, refers to Angle class II occlusion in which the hypoplastic and retruded mandible leads to an overbite and dental malocclusion. It is important to note that prominence of the chin confers strength to the jaw–neck contour and makes the transition between facial and cervical aesthetic units more pronounced, thus giving the illusion of a more acute cervicomental angle (12).

Patients with a class VI neck have an inferiorly positioned hyoid bone that creates an obtuse cervicomental angle. Diagnosis is made by palpating the hyoid bone and evaluating its relationship to the mandible and clavicles. As stated earlier, the hyoid bone should ideally reside at the level of the third or fourth cervical vertebra. A low-positioned hyoid bone is a major limiting factor in optimal aesthetic correction of the aging neck unless more aggressive surgical treatment is undertaken.

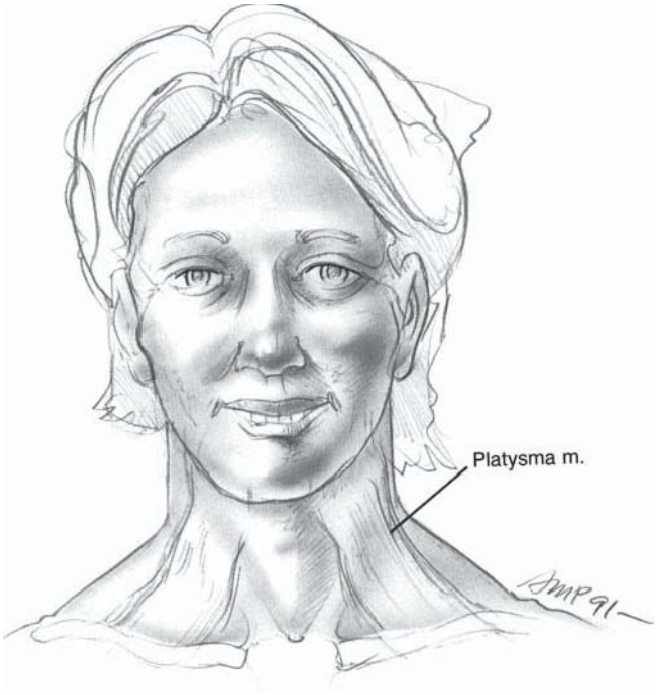

Figure 189.6 The medial and lateral borders of the platysma muscle can be better delineated by having the patient grimace with the teeth clenched.

TREATMENT

After careful analysis of each anatomic factor contributing to the individual patient's deformity, a targeted surgical treatment plan can be instituted (Table 189.1). It should be noted that a weak chin can be a compounding factor in any of the classification groups. In addition to treating the soft tissue abnormalities, an alloplastic chin implant should be strongly considered in any patient with evidence of microgenia. Again, in patients with significant retrognathia, chin

TABLE 189.1 TARGETED SURGICAL TREATMENT PLAN

Modified Dedo's Classification	Treatment Options
Class I (minimal deformity)	• No surgical intervention • "S lift" • ± Chin augmentation
Class II (laxity of cervical skin)	• Rhytidectomy • ± Chin augmentation
Class III (excess fat)	• Cervical liposuction • ± Anterior platysmaplasty • ± Rhytidectomy (for skin laxity) • ± Chin augmentation
Class IV (platysmal banding)	• Rhytidectomy (with anterior platysmaplasty) • ± Cervical liposuction • ± Chin augmentation
Class V (microgenia or retrognathia)	• Chin augmentation (microgenia) • Bony osteotomy and advancement (retrognathia)
Class VI (low hyoid or other unfavorable anatomy)	• Treat soft tissue abnormalities with standard techniques (with realistic expectations) • ± Division of suprahyoid musculature from mandible • ± Suturing of anterior digastric muscles together • ± Partial excision of anterior digastric muscles • ± Chin augmentation

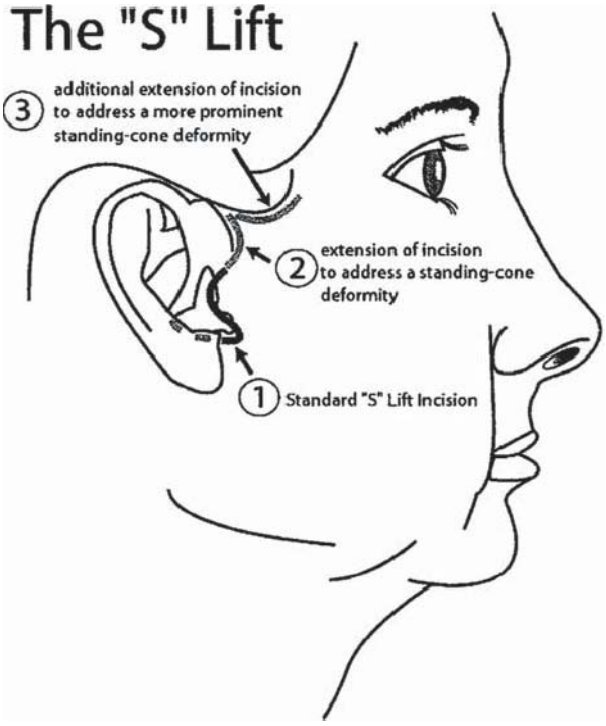

Figure 189.7 The configuration of the incision resembles an S shape. The abbreviated length is suitable for younger patients who do not have significant skin redundancy but only some incipient jowling. To address a standing-cone ("dog-ear") deformity that may arise, the anterior skin incision can be extended up to (or all the way around) the temporal tuft, as needed.

augmentation alone may not give optimal aesthetic results, and bony advancement techniques should be considered.

In young patients with minimal deformity (class I), the most prudent course of action would be simply to wait before any surgical intervention is offered. In the patient with good skin and muscle tone, a simple weight loss program could be sufficient (8). The improvement gained by surgical intervention at this time would be minimal; however, intervention may delay soft tissue ptosis from developing as quickly. In the fastidious patient with realistic expectations, a limited rhytidectomy (S lift) can be considered (Fig. 189.7). An incision that extends only under the ear lobule in a lazy-S configuration is made, allowing a limited SMAS suspension and excision of skin without committing the patient to a standard rhytidectomy (16).

In patients with redundant skin of the cervical region (class II), a standard cervicofacial rhytidectomy is generally considered the treatment of choice. To remove excess skin and to efface jowling along the inferior mandibular border, a SMAS imbrication technique is used to provide long-lasting improvement of the contour of the lower one-third of the face and neck. A special note should be made for the "turkey gobbler" deformity, which is commonly seen in men. Multiple techniques have been described to remove the excess skin that often occurs in isolation (12,17). The midline scars that result from these procedures are well hidden in the thick, hair-bearing submental skin of men.

In patients demonstrating isolated fat accumulation (class III), cervical liposuction is the procedure of choice. In the younger patient with good skin elasticity and no platysmal pathology, liposuction can be performed as an isolated procedure. The mild dermal injury inflicted by the liposuction cannula promotes contraction of the overlying skin, thus obviating the need for skin excision in patients with good skin elasticity. Recent reports have suggested that other liposuction techniques (e.g., tumescent, liposhaving, ultrasound assisted) are superior to traditional liposuction. The tumescent technique, which has been applied with success for body liposuction, is less than ideal for the cervicofacial region because the distortion engendered renders assessment difficult, and the persistent edema that arises is an unwarranted drawback. The risk of third space volume shifts further compounds the problem with the tumescent method. Although safety and efficacy of treatment with the liposhaver has been documented in a multi-institutional review (18), the device's ability to cut through muscle and other soft tissue (including blood vessels and nerves) creates the potential for significant complications. The ultrasound method suffers from the attendant risk of increased thermal injury (if internally applied) and neural and cutaneous flap injury. These adverse outcomes are not definitively established because no controlled studies exist, but they remain of concern nevertheless. In essence, these additional technologies have not proved themselves more useful or beneficial than traditional liposuction, even in experienced hands.

The early fourth decade appears to be a transition time when skin elasticity decreases and liposuction alone can result in less than optimal results. Liposuction performed in isolation in a patient with poor skin elasticity and a large accumulation of fat can lead to poor redraping and contraction of the anterior cervical skin, causing postoperative "rippling" and other deformities (13). These patients are typically better candidates for rhytidectomy in conjunction with submental liposuction and anterior platysmaplasty (see "Surgical Technique: Submentoplasty"). The combination of suction lipectomy and rhytidectomy can also predispose the patient to the development of postoperative platysmal banding, even if anterior platysmal banding is not clinically evident preoperatively (3,13). Anterior platysmaplasty, therefore, is suggested when performing liposuction and rhytidectomy concurrently to avoid the untoward sequela of postoperative platysmal banding.

Class IV patients are those with platysmal abnormalities (e.g., muscle ptosis, atrophy, and midline banding). These patients are best served with a rhytidectomy and anterior platysmaplasty. The combination of SMAS suspension rhytidectomy and anterior platysmaplasty creates a "cervical corset" to support the underlying soft tissues. Additionally, if excess fat is also apparent, liposuction can be performed in conjunction with the above procedures.

Class V patients are those with microgenia or retrognathia. As above, a weak chin may be seen in conjunction with other soft tissue abnormalities and should be

treated appropriately after determining the occlusal status. Retrognathia is typically corrected with mandibular osteotomies and bony advancement, whereas microgenia is corrected with alloplastic chin augmentation. It should be noted, however, that it is acceptable in certain patients with *mild* retrognathia to perform chin augmentation instead of pursuing the more aggressive treatment with bony advancement. By evaluating the patient's occlusion and distinguishing between true retrognathia and microgenia, the appropriate treatment can be offered to the patient to optimize the aesthetic outcome.

Class VI patients are those with a low-positioned hyoid bone or other unfavorable anatomy such as anterior digastric muscle hypertrophy and submandibular gland ptosis. Preoperatively, these patients should understand the limitations of their particular anatomy so they have a realistic expectation of the outcome. They should be treated appropriately with standard methods; however, more aggressive techniques may be considered to optimize the aesthetic outcome.

Maneuvers to reposition the hyoid include transecting the suprahyoid musculature from the inferior border of the mandible (19) as well as suturing the anterior bellies of the digastric muscles together to create a new vector of pull (9). To treat digastric muscle hypertrophy, tangential shaving of the anterior bellies of the digastric muscles can also be performed (9).

Ptotic submandibular glands, which are commonly seen in elderly patients, represent a limitation to optimal aesthetic outcome. Surgical removal or reduction is certainly beyond the scope of aesthetic surgery; however, by creating a well-supported "cervical corset" with SMAS suspension and anterior platysmaplasty, the ptotic glands will be elevated to a more favorable position.

Surgical Technique: Submentoplasty (Submental Liposuction and Anterior Platysmaplasty)

In the senior author's hands, the submentoplasty (16) is performed at the outset before a rhytidectomy because the medial borders of the platysma muscle are difficult to unite after the lateral pull of the rhytidectomy has been completed. Similarly, submental liposuction precedes platysmaplasty because the removal of adipose and the concomitant undermining permit visualization of the skeletonized platysma. Chin augmentation follows the submentoplasty and precedes the rhytidectomy because the submentoplasty incision is used as a point of entry for chin implantation. Further, vigorous submentoplasty can disturb the position of the implant if done after chin augmentation.

The submentoplasty begins with a straight incision about 1 to 2 mm posterior to the submental crease that extends typically 2 cm in breadth (Fig. 189.8). The incision should fall slightly posterior to the submental crease because placement of the incision directly in the crease will deepen over time so that the line may become conspicuous. Additionally, if chin augmentation is to be performed, the incision should be placed even further posteriorly (4 to 5 mm) from the submental crease. This is necessary because following placement of the chin alloplast, the anterior portion of the incision has a tendency to move cephalically, potentially creating a visible incision near the inferior edge of the mandible.

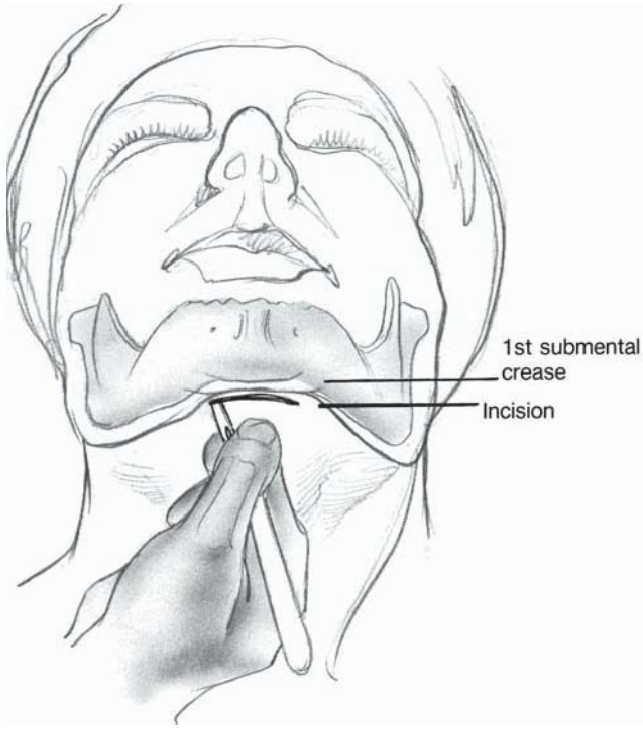

Figure 189.8 The submental incision is placed just behind (1 to 2 mm) the submental crease. If chin augmentation is to be performed, the incision should be placed even further posteriorly (4 to 5 mm behind the crease) to prevent a conspicuous postoperative scar.

After the initial incision through the skin, wide double-hooked retractors are placed in the superior and inferior aspects of the wound for proper tension and retraction. The assistant retracts the superior flap while the surgeon retracts the inferior flap. The surgeon then performs wide undermining of the flap from just inferior to the jawline (1 to 2 cm below) across the submental region to the contralateral jawline using a pair of Metzenbaum scissors in the subcutaneous plane (Fig. 189.9). Dissection should not pass directly over the jawline to minimize risk of injury to the marginal mandibular nerve. Although the nerve should be protected under the platysma muscle in most cases, an attenuated or dehiscent platysma layer may predispose the nerve to inadvertent harm. The depth of dissection should leave approximately a 3- to 4-mm-thick skin–subcutaneous flap to avoid an uneven contour that may develop after liposuction and to ensure vascularity to the overlying skin flap. The lateral extent of the undermining should be to the anterior borders of the sternocleidomastoid muscle bilaterally.

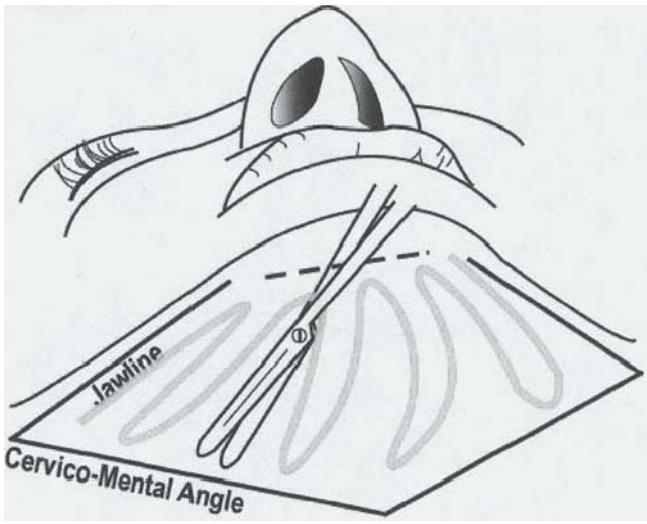

Figure 189.9 Wide undermining of the flap is performed from just inferior to the jaw line (1 to 2 cm below) across the submental region to the contralateral jaw line using a pair of Metzenbaum scissors in the subcutaneous plane.

After the submental region has been widely undermined, a liposuction cannula can be introduced with the aperture *always* facing deep, away from the flap, to avoid the development of an irregular skin contour from suctioning the overlying flap. Furthermore, the vascular supply of the flap emanates from its deep surface, and liposuction under the flap can lead to vascular compromise. The liposuction canister pressure should be set at 29 mm Hg before initiating the procedure. The surgeon should ensure that the instrument is evenly passed over the entire expanse of the undermined submental region, with perhaps additional treatment centrally where a greater adipose deposit may be observed (Fig. 189.10).

Following liposuction, subplatysmal lipectomy and platysmaplasty are performed. With headlight illumination and a Converse retractor, the surgeon should properly visualize the medial terminal fibers of the platysma muscle. If the platysma muscle continues to be obscured by overlying adipose despite liposuction, a selective lipectomy is performed with scissor dissection. A narrow strip along the medial borders of the platysma is often removed sharply to aid in exposing the subplatysmal fat layer. This step is not performed if the platysma is determined to be minimally redundant and the consequent tension of closure would be too great with additional platysmal resection. If the platysma borders appear widely separated, sufficient undermining is performed to facilitate a relaxed closure. Lipectomy limited to the central subplatysmal compartment is then performed. The anterior digastrics serve as the lateral limit of the dissection. While more aggressive lipectomy may maximize aesthetic outcome, it increases both the likelihood of poorly controlled and visualized hemorrhage and the risk of injury to the marginal mandibular branch of the facial nerve. Additionally, a "cobra deformity" may result from overaggressive fat resection.

Before the platysma muscle can be approximated, the inferior extent of the platysmal closure should be identified (the cervicomental angle, typically located at the thyroid notch). After the platysma borders have been properly exposed and dissected, the anterior free edges are reapproximated with 4-0 polydioxanone, or equivalent, suture in a running, nonlocking fashion (Fig. 189.11). The suture should not be tied very tightly to avoid the complication of a bunched appearance in this area after resolution of edema. To reiterate, the suture should be started at the level of the thyroid notch and proceed in a superior direction. If a chin implant is not planned, then the submental incision is closed with a 6-0 running, locking polypropylene suture (Fig. 189.12).

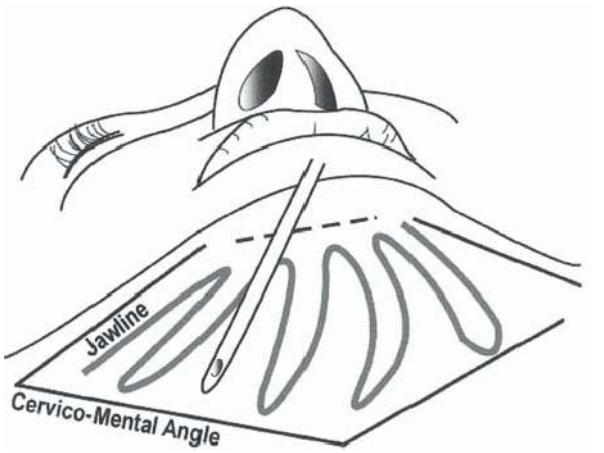

Figure 189.10 The liposuction cannula should be evenly passed over the entire expanse of the undermined submental region.

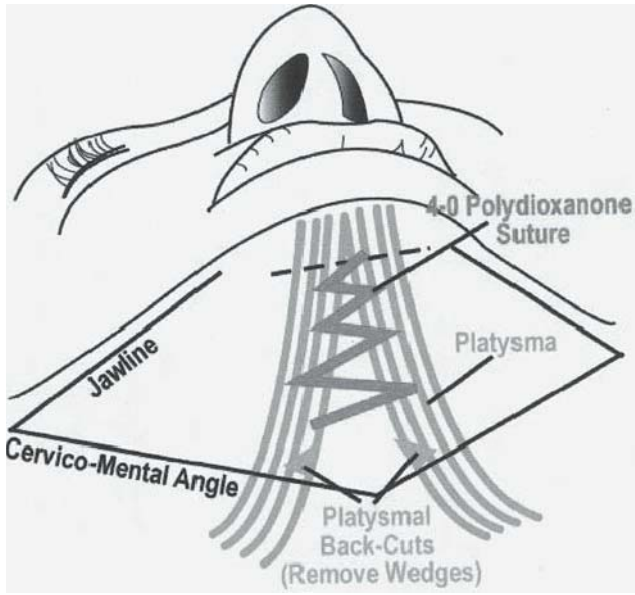

Figure 189.11 After exposure of the anterior platysmal borders, the free edges are approximated with 4-0 polydioxanone suture in a running, nonlocking fashion. The suture should be started approximately at the thyroid notch or cervicomental angle, immediately superior to the platysmal back-cuts.

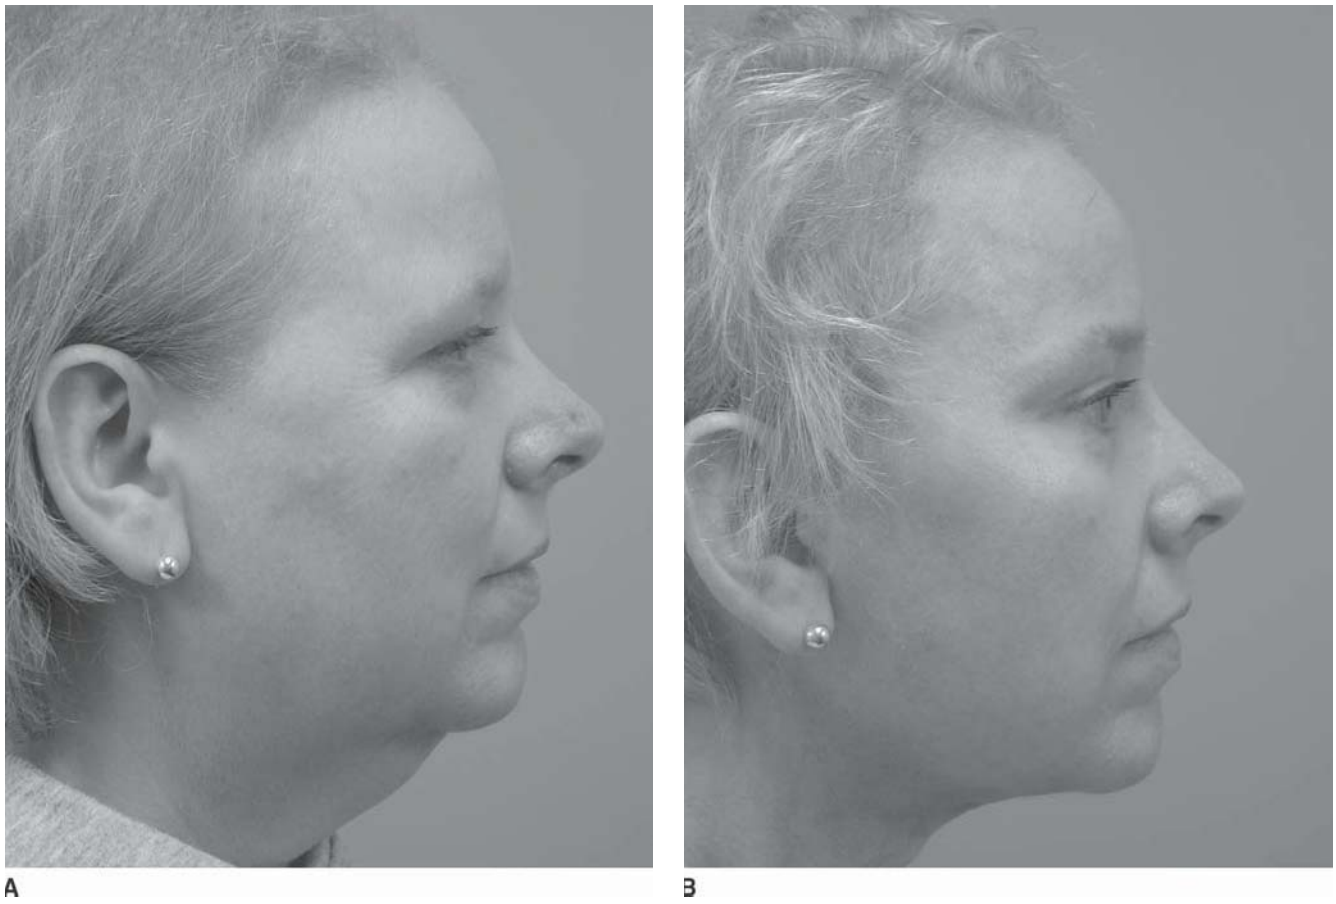

Figure 189.12 **A,B:** The pre- and postoperative photographs of a patient who had cervical liposuction–submentoplasty and SMAS imbrication rhytidectomy demonstrate effacement of the jowls and creation of a cervicomental angle of 90 degrees.

COMPLICATIONS AND MANAGEMENT

Early Complications

Early complications following submental liposuction and anterior platysmaplasty include hematoma, seroma, sialocele, infection, contour irregularity, and injury to the marginal mandibular branch of the facial nerve. Hematoma, seroma, or sialocele is seen in less than 1% of patients when liposuction is used as a primary procedure (20). Sialocele is more commonly seen when liposuction is performed over the parotid gland bed in association with a rhytidectomy. Treatment for a sialocele includes pressure dressings, anticholinergics, and repeat aspiration or drainage. A seroma is a collection of serous fluid that occurs in the submental region. They are best treated with needle aspiration and placement of a pressure dressing to prevent reaccumulation.

A large expanding hematoma is an emergency, and the patient should be returned to the operating room for wound exploration, irrigation, and control of all bleeding sites. Smaller hematomas can be managed in the office setting. A limited hematoma discovered on the first postoperative day can be treated by direct aspiration with an 18-gauge needle or by using a gauze sponge to roll out the blood through a small stab incision over the area of concern. A discrete collection discovered somewhat later may require 7 to 10 days to liquefy before it can be aspirated. Persistence of a hematoma predisposes the patient to infection and skin flap necrosis. Because blood is an excellent culture medium, all patients with a hematoma should be placed on prophylactic antibiotics.

Ideally, the best treatment for a hematoma is prevention. In the preoperative phase, the patient's blood pressure should be well controlled. All preoperative medications that could compromise effective coagulation must be ceased for a period of 2 weeks pre- and 2 weeks postoperatively, including prescription medications (e.g., warfarin), over-the-counter medications (e.g., aspirin, ibuprofen), herbal medications (e.g., St. John's wort, ginkgo biloba), supplements (e.g., vitamin E, fish oil, omega-3 fatty acids), and alcohol. In all circumstances, a male patient requires the surgeon to be at an increased level of attention, given the richer vascularity that the hair-bearing skin of the lower face exhibits and the concomitant risk of hematoma formation.

Infections are rare, occurring in less than 1% of patients (20). Most surgeons, however, elect to put their patients on

a prophylactic antibiotic regimen despite the lack of scientific evidence to support their use. An alloplastic implant (e.g., chin implant) can be a source for infection. If an abscess develops at the site of implantation, it is almost assured that the implant will require removal. Removal of the implant with reinsertion later when the infection has subsided is the best treatment policy. At the first sign of an infection, a dose of intravenous antibiotics is administered to ensure immediate, proper therapeutic levels, followed by a full regimen of broad-spectrum oral antibiotics until the infection clears.

Early contour irregularities following cervical liposuction are the rule rather than the exception. Most resolve as healing progresses and edema lessens. Patients should be reassured during the first several weeks postoperatively that irregularities generally smooth out over time.

Permanent injury to the marginal mandibular branch of the facial nerve is rare, as long as the surgeon remains superficial to the platysma muscle. Temporary paresis can occur with aggressive liposuction in a patient with an attenuated, thin platysma muscle, which typically resolves within 6 months.

Late Complications

Late complications include scarring, platysmal banding, and irregular neck contour. Hypertrophic or wide scars are rarely seen in the submental incision, but are more commonly seen with rhytidectomy incisions secondary to excessive tension on the skin closure. Additionally, patients with Fitzpatrick V or VI skin types are more susceptible to the development of hypertrophic scars and keloids. Management should include injection of the scars with triamcinolone (10 mg/mL) at 3- to 4-week intervals until improvement is noted. More frequent injections carry the risk of dermal atrophy and hypopigmentation. Additionally, the pulsed dye laser has been shown to be a useful adjunct (16). If the scar persists despite these measures, scar revision may be considered after a 12-month interval.

Platysmal banding, which can occur postoperatively, is most commonly due to unrecognized, and therefore untreated, preoperative platysmal banding. This is most commonly seen in patients with submental obesity and redundant skin (21). To avoid the complication, preoperative recognition is essential. Platysmal banding can be treated primarily, or secondarily, with anterior platysmaplasty.

An irregular neck contour can result from direct, sharp lipectomy, or from an uneven liposuction technique. Especially in the immediate submental region, overzealous excision of fat can produce a central concavity. A "cobra deformity" describes the situation in which a patient has a central submental concavity from overzealous fat removal in combination with prominent platysmal bands, resembling a cobra about to strike. This deformity is even more pronounced when the anterior borders of the platysma muscle are not united following central lipectomy. Irregularities can be prevented by widely undermining the cervical skin with a 3- to 4-mm layer of fat remaining attached to the overlying dermis and by gauging the thickness of this layer with bimanual palpation during liposuction. Additionally, to avoid further irregularities, the surgeon must make sure the aperture of the liposuction cannula is always facing *away* from the dermis.

Even in the best of hands, neck irregularities still occur. If necessary, small localized depressions can be treated with a soft tissue filler (e.g., autologous fat); however, large depressions may require placement of dermal graft materials (e.g., cadaveric acellular dermis) for correction (20). Again, prevention is the best treatment.

HIGHLIGHTS

- The anatomic factors that contribute to an ideal cervical contour include a strong chin, a distinct mandibular border, a cervicomental angle of 105 to 120 degrees, a visible subhyoid bone depression, a gentle indentation at the thyroid notch, and visible anterior borders of the sternocleidomastoid muscles.
- Several anatomic elements contribute to the appearance of an aging neck, including skin, fat, platysma muscle, chin projection, and hyoid bone position.
- Each anatomic element contributing to the deformity should be delineated preoperatively and sequentially addressed to provide an optimal aesthetic outcome.
- A classification system can be used to categorize patients and to target treatment to their specific needs (Table 189.1).
- The rhytidectomy and submentoplasty procedures are the cornerstones of treating the aging neck.
- Early complications of surgery on the aging neck include hematoma, seroma, sialocele, infection, contour irregularity, and injury to the marginal mandibular branch of the facial nerve.
- Late complications include scarring, platysmal banding, and irregular neck contour.

190 Otoplasty: Anatomy, Embryology, and Technique

Steven Ross Mobley *Nathan Todd Nelson Schreiber*

In addition to its function in directing sound to the tympanic membrane, the ear plays a complementary role in one's appearance. If abnormal in appearance, however, the ear can command unwanted attention, drawing an observer's eyes away from the rest of the face. Classically, auricular anomalies have resulted in significant social stigma. In a criminology text from 1876, author Cesare Lombroso wrote, "nearly all criminals have jug ears" (1); a number of overtly discriminatory texts from this period contain overtly belittling references to prominent ears as well (2). Although such beliefs are, for the most part, not consciously encouraged today, they persist in more subtle forms. In popular culture, large ears are often exaggerated in jest for cartoons and caricatures. For children especially, prominent or malformed ears may be the subject of ridicule, possibly affecting self-esteem and psychosocial development. It is for this reason that surgical correction of the anomalous ear is often sought.

The goal of otoplasty is to create a more natural appearance and position of the ear. Its origins can be traced back to India in 800 BC, when reconstruction of the lobule using a local cheek flap was first described by Indian surgeon Sushruta (3). Reconstruction of larger ear defects using postauricular scalp flaps was not described until centuries later in textbooks, by Italian surgeon Gaspare Tagliacozzi in 1597, and again by Prussian surgeon Johann Friedrich Dieffenbach in 1845 (4–6). The first truly cosmetic otoplasty, however, was performed in 1881, by American surgeon Edward Ely, on a 12-year-old boy who was ridiculed for having a prominent ear (7,8). In the ensuing years, multiple variations of this operation have been described and provide a number of techniques that may be used to create a more anatomically natural-appearing ear. Given the multitude of techniques, one must understand normal auricular anatomy as well as the goals of surgery in order to successfully perform otoplasty.

ANATOMY AND EMBRYOLOGY

The auricle is essentially an extension of fibroelastic cartilage from the external auditory canal that is covered by perichondrium and a thin layer of skin. The skin is directly adherent to perichondrium anteriorly but is separated from perichondrium by loose areolar tissue posteriorly. Cartilage is deficient at the lobule as well as between the tragus and the beginning of the helix anteriorly. Projections of cartilage from the anterior and inferior ends of the helix are called the spina helicis and the cauda helicis, respectively. Attached to portions of the cartilage itself are six internal auricular muscles: the helicis major, helicis minor, tragicus, and antitragicus along the lateral side of the cartilage and the transversus auriculae and obliquus auriculae along the medial side of the cartilage. Three external auricular muscles, anterior, superior, and posterior, provide additional fixation to the temporal bone and, through the facial nerve, the ability to move one's ear. Auricular sensation is provided by multiple nerves. C2 and C3 through the greater auricular nerve provide sensation posteriorly at the helix, antihelix, and lobule. Cranial nerves IX and X provide sensation to the conchal bowl and posterior external auditory canal. The auriculotemporal branch of the mandibular division of the fifth cranial nerve provides sensation to the tragus, superior helix, and superior and anterior external auditory canal. The superficial temporal, posterior auricular, and occipital branches of the external carotid artery provide the auricle's arterial supply, while the superficial temporal vein, retromandibular vein, external jugular vein, and, in some cases, the mastoid emissary vein provide venous drainage. Lymphatic drainage occurs through the parotid, posterior auricular, and cervical levels 2 and 5 lymph nodes (9). The normal anatomy of the auricle is shown in Figure 190.1.

The external ear develops from six swellings called hillocks of His, which are present at 6 weeks' gestation. The first

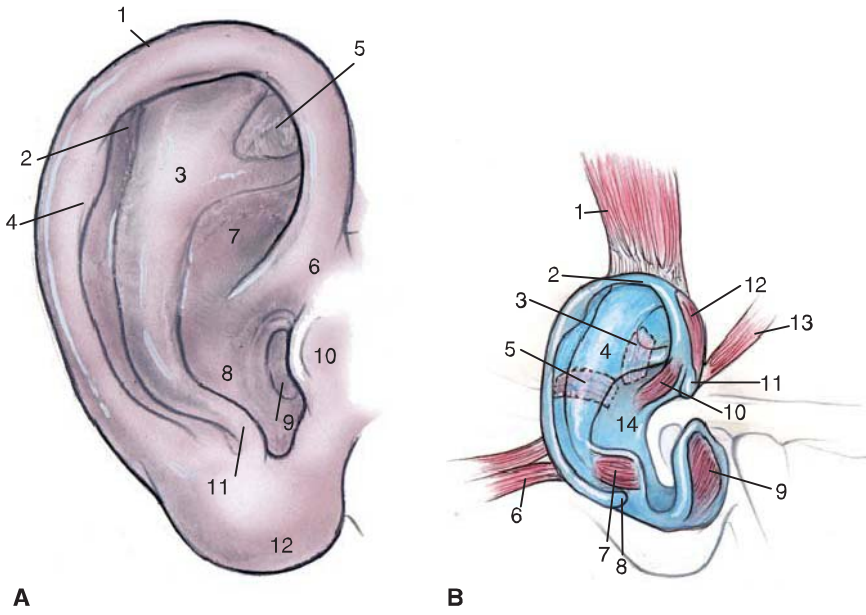

Figure 190.1 **A:** Normal external auricular anatomy. *1*, Helix; *2*, scaphoid fossa; *3*, antihelix; *4*, auricular (Darwin) tubercle; *5*, triangular fossa; *6*, crus helicis; *7*, cymba concha; *8*, cavum concha; *9*, external auditory meatus; *10*, tragus; *11*, antitragus; *12*, lobule. **B:** Normal external and internal auricular musculature. *1*, Auricularis superior; *2*, helix; *3*, obliquus auriculae; *4*, antihelix; *5*, transversus auriculae; *6*, auricularis posterior; *7*, antitragicus; *8*, cauda helicis; *9*, tragicus; *10*, helicis minor; *11*, spina helicis; *12*, helicis major; *13*, auricularis anterior; *14*, concha.

three hillocks of His develop from the first branchial arch into the tragus, helical crus, and helix, while the second three hillocks of His develop from the second branchial arch into the antihelix, antitragus, and lobule (Fig. 190.2). The hillocks of His are fused by 12 weeks' gestation and reach a final shape around 20 weeks' gestation (9,10).

The ear generally reaches 85% of its ultimate vertical height, 5 cm, by 3 years of age and is nearly full size, 6 cm, by 5 years of age. From this point on, the helix will grow relatively little, while the lobule will grow to a much greater degree, disproportionately lengthening with advancing age (9,11). In general, men have a slightly larger pinna and greater distance from the lateral orbital rim to helical root than do women; these distances are usually equal for each individual and on average measure 6 cm. Ear width, on the other hand, is usually just over half its height. Ear protrusion can be measured by either its distance from or angle to the scalp. The average distance from the helical rim to the scalp is 1.5 to 2 cm while the average auriculocephalic angle is 20 to 35 degrees (Fig. 190.3) (12,13).

AURICULAR ANOMALIES

Etiology and Classification

Auricular anomalies occur in approximately 5% of the population, either in isolation or as part of a syndrome (14). Most auricular anomalies are sporadic, but some are hereditary. Their etiologies include genetic mutations, *in utero* insults from exogenous factors, compression from external forces, and abnormal intrinsic ear musculature. There is a wide range of degree to which these anomalies can occur, and there are a number of classification systems, based on extent of anomaly and extent of surgical intervention, that have been devised to group them. Many of the early classification systems were combined by Weerda in 1988, dividing anomalies into first-, second-, and third-degree dysplasia (Table 190.1) (15). In 1997, Tan et al. proposed an even more simplified system that takes ear molding techniques into account and divides anomalies into two groups: deformational auricular anomalies and malformational auricular anomalies. Deformations result from external forces that cause abnormal architecture of tissue that is otherwise normal, while malformations result from abnormal tissue development that leads to abnormal architecture. Deformational auricular anomalies can be manually reduced to create a nearly normal appearance and can be treated early on with ear molding techniques or later with surgery. Malformational auricular anomalies, on the other hand, cannot be manually reduced to a normal appearance. These anomalies require surgery but can, in some cases, be partially treated with ear molding techniques if they also contain deformational components (16,17). In general, these classification systems are useful in clinical evaluation and determining the types of intervention that will be most helpful. However, it is important to keep in mind that auricular anomalies do not always fit cleanly within a single category and a number of treatment options should be considered in every case.

TABLE 190.1 AURICULAR DYSPLASIA CLASSIFICATION SYSTEM BY WEERDA

	Anatomic Definition	Surgical Definition
First-degree dysplasia	Most structures of the normal auricle are recognizable Minor deformities	Reconstruction does not require the use of additional skin or cartilage
Second-degree dysplasia	Some structures of the normal auricle are recognizable Moderate deformities	Partial reconstruction requires the use of additional skin and cartilage
Third-degree dysplasia	None of the structures of the normal ear are recognizable Severe deformities	Total reconstruction requires the use of additional skin and large amounts of cartilage

Deformations

Stahl Ear

Stahl ear, alternatively known as Satyr ear, Spock ear, and Vulcan ear, is a first-degree or deformational auricular anomaly characterized by an abnormal transverse crus from the antihelix to the posterior superior helical rim and, often times, an absent superior crus (Fig. 190.4). It may be caused by external forces *in utero* or perhaps an abnormal course of the transversus auriculae, one of the intrinsic muscles of the ear (18). Stahl ear can be treated with molding techniques, suturing techniques, or excision of abnormal cartilage (19,20).

Cryptotia

Cryptotia, a term that means hidden or pocket ear, is a condition in which the superior helical cartilage is buried under the skin (Fig. 190.4). This deformity is thought to be caused by an abnormal attachment of the superior auricular muscle to the scapha rather than to the triangular fossa as well as a shortened transversus auriculae, effectively pulling the superior helix under the skin during development. This condition can be treated with molding or by releasing the superior helix from the scalp with skin grafting, advancing the resulting postauricular defect, performing a Z-plasty, or performing a trefoil flap, a flap consisting of three symmetric triangles based at the superior auricle that is used to cover the posterior cartilage upon release (21,22).

Prominent Ear

The prominent ear is a type of deformational auricular anomaly characterized by an absent antihelical fold and deep conchal bowl (Fig. 190.4). These deformities increase the auriculocephalic angle and the distance from the scalp to the helix. In addition, the prominent ear will often demonstrate a number of secondary findings, including a large helical root, excessive lobule projection, and inadequate helical curl. This condition has been associated with an abnormally distal insertion of the antitragicus muscle that extends along the anterior surface of the ear from the antitragus to the antihelix, pulling the helix laterally during development (23). Ear molding techniques may be successful early in life but, unlike with certain other ear deformities, often fail to adequately treat this condition if older than 3 months (16,24). This failure may be related to resistance created by the antitragicus muscle. In many cases, surgical intervention is required for definitive treatment.

Malformations

Constricted Ear

Constricted ears are characterized by partial absence of cartilage at the upper third of the helical rim and sometimes

the concha, resulting in a purse-string effect at the helix (Fig. 190.4). This type of malformation can be classified as either first- or second-degree dysplasia depending on its severity. Constricted ears will demonstrate a combination of helical lidding, protrusion, low position, and decreased size. This category is variably labeled as cup, lop, and cockleshell ear, among other names, in various sources. This malformation can be found in a number of inherited syndromes but is usually sporadic when isolated.

The findings in constricted ears can be divided into three groups based on severity and the treatment that is needed for correction. Mild constriction involves the helix only and can often be corrected with molding techniques as a neonate or later with an otoplasty technique similar to that used for prominent ears. Moderate constriction and severe constriction, however, are defined by hypoplasia of both the helix and scapha and require surgical intervention. Moderate constriction often requires a V-Y helical

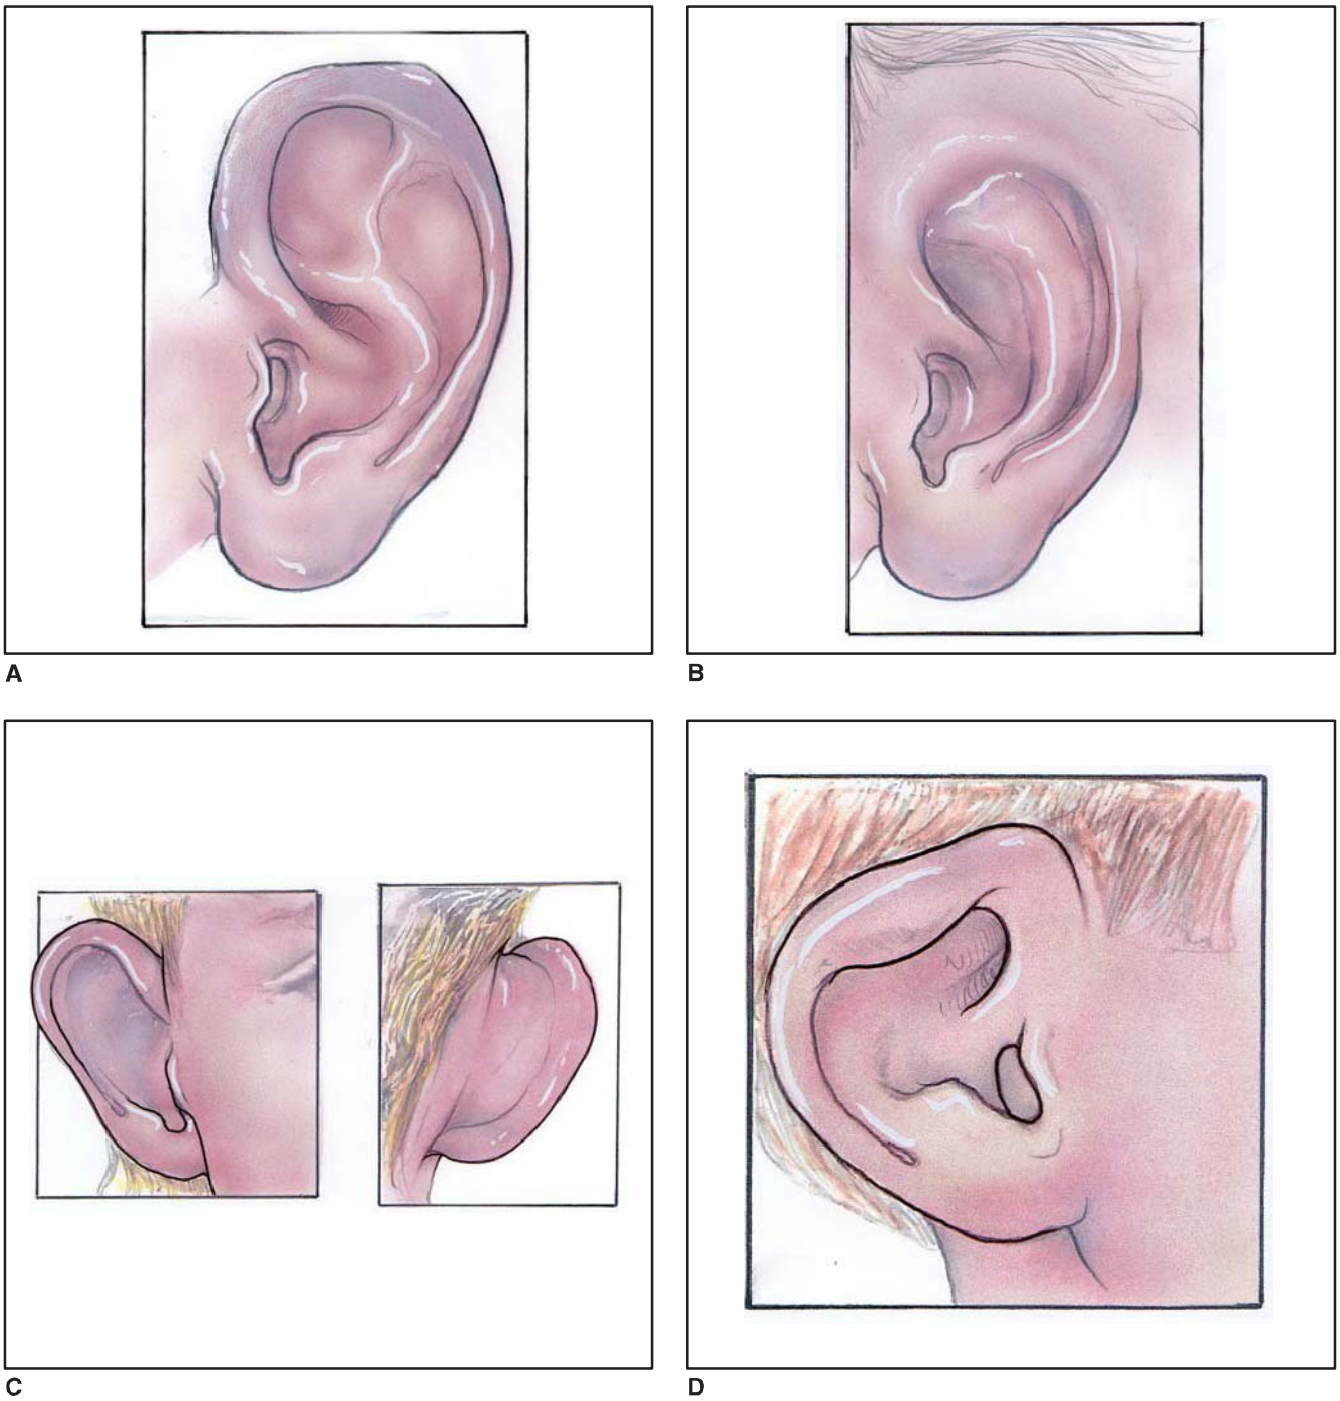

Figure 190.4 **A:** Stahl ear. **B:** Cryptotia. **C:** Prominent ear. **D:** Constricted ear.

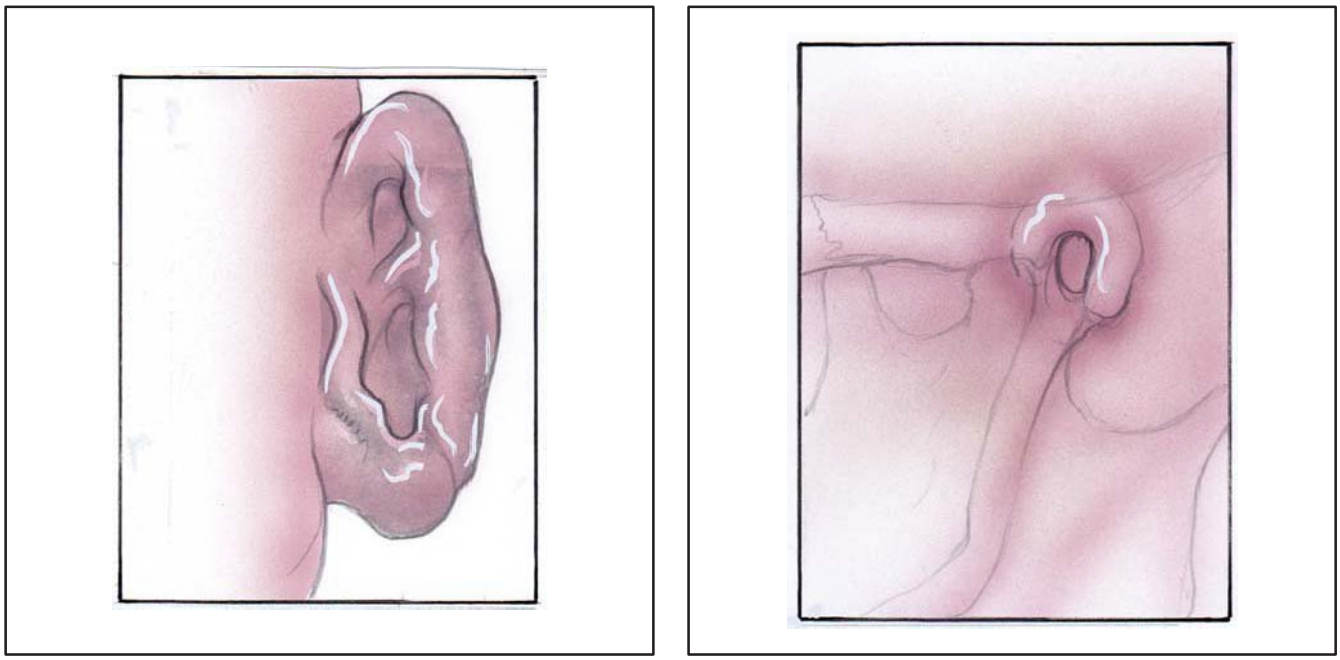

E F

Figure 190.4 (*Continued*) **E:** Microtia. **F:** Anotia.

root advancement as well as conchal or sometimes rib cartilage grafting (25). Severe constriction requires subtotal auricular reconstruction with rib cartilage grafting and postauricular skin recruitment (26,27).

Microtia

Microtia is hypoplasia of a majority of the pinna, while anotia is the complete absence of the pinna (Fig. 190.4). These malformations may or may not spare the external auditory canal and are types of third-degree dysplasia. Total auricular reconstruction for microtia and anotia is not addressed in this chapter.

Psychosocial Issues

There have been a handful of studies and anecdotal observations regarding the psychosocial impact of various facial anomalies. The majority of these studies, however, concern children with significant craniofacial malformations. One study that did examine children with isolated ear anomalies noted a 40% incidence of ear anomaly in children who were residents of the Mental Health Center of Norfolk, the majority of which were noted to have had adjustment reactions in childhood or adolescence (12). It is important to note, however, that no evidence of causation could be determined. A more recent study by Sheerin et al. compares children with prominent ears to children with facial port-wine stains and suggests that self-esteem, social, and attention problems may be even more severe in the group with prominent ears. Although the groups were small, the study's authors believe this difference could in part be due to decreased familial support and recognition of deformity in those with prominent ears, who may be thought of as having an exaggeration of the normal rather than a true deformity. Regardless of the reason for this difference, this study suggests that children who are bothered by their ears are much more likely to have psychosocial problems (28). Further studies may help to determine if otoplasty can help to improve psychosocial adjustment in this population.

PATIENT SELECTION

Initial Evaluation

There are several steps that should be performed when evaluating a patient with auricular dysplasia. The patient's unique ear anatomy should be analyzed, goals and expectations should be addressed, and treatment options should be considered that best meet the agreed-upon goals.

First, the ears should be photographed with full-face and close-up frontal, oblique, lateral, and posterior views. After physical exam, these images are an important adjunct for evaluating the anatomic causes of deformity as well as any differences on one side compared to the other. These images can be viewed with the patient to facilitate a discussion about goals and expectations for treatment, realistic outcomes, and the appropriate techniques that could be employed to achieve this result. In addition, measurements of ear height, width, and distance from the scalp as well as the auriculocephalic angle are useful. Together, these images and measurements can be used to objectively document postoperative and long-term follow-up changes (29).

Nonsurgical Treatment

If a deformational auricular anomaly is identified in a neonate or, according to some, select older individuals, molding techniques should be considered. These techniques usually involve placing a bendable splint along the helical rim, antihelix, and conchal bowl and taping it in place to hold the ear in an appropriate position for 2 to 12 weeks. Molding is able to correct up to 90% of deformational auricular anomalies if started within the first week of life (30,31). Most authors only advocate molding for neonates, but there have been some reports of successful treatment of older children (32). In general, after 3 weeks of age, molding is less successful. Yotsuyanagi noted that improvement declines from 80% if molding is started at 1 to 3 months of age, to 33% if molding is started after 9 years of age. In general, molding failures in this study were most common with moderately and severely constricted ears as well as prominent ears (24,33).

In 2011, Leclere et al. reported a series of 17 patients with prominent ears and an average age of 34.5 years who underwent laser-assisted cartilage reshaping, a new technique in which the ear is treated with an erbium/glass laser to reshape the cartilage without any anesthesia and molded into the desired shape with a silicone splint. The splint is then worn at all times for 2 weeks and then at night only for 4 weeks. At a 30-month follow-up appointment, two patients had incomplete shape correction, which was thought to be related to incorrect splint design and contact dermatitis, and five patients had slight ear asymmetry. Overall, 10 of 17 patients obtained the desired result (34). Although only small series have been published about this technique, it may become a preferred method of treatment in the future.

Ear molding is certainly an attractive option for neonates and perhaps select older children or adults who do not wish to undergo surgery. Importantly, one must gauge a patient's ability to tolerate the discomfort, time, and effort required to wear an ear splint consistently for a period of time. In the future, laser-assisted cartilage reshaping may significantly increase the success rate of molding, although more studies are needed. Surgery can always be performed at a later date for those who do not achieve the desired correction with molding alone.

Surgical Candidates

Prominent ears generally result from a combination of insufficient antihelical fold and excessively large conchal bowl and have been defined in a number of ways. Some define ear prominence as an auriculocephalic angle greater than 40 degrees or a helix to scalp distance greater than 2.5 cm (35). Of the two major components of prominent-ear deformity, unfolding of the antihelical fold has been found to contribute to 73% of ear prominence.

Regardless of published standards, prominent ears, for many people, are primarily a psychological concern, and most will present with their own ideas of how their ears should be. For example, men may present wanting ears very close to the scalp because of balding or a desire to wear their hair short. Women, on the other hand, may tolerate less correction because of longer hair and a greater ability to cover their ears. Alexander et al. (36) found discordance between researcher- and subject-defined ear prominence, with the principal investigator reporting ear prominence in 10% of subjects, but self-reported ear prominence in only 2%, leading the authors to conclude that an ear is prominent when the patient says it is. In a minority of patients, however, prominent ears may interfere with the ability to perform a job or wear safety equipment. Salgado reported a case series of U.S. Army soldiers who underwent otoplasty because of the inability to wear Kevlar helmets without developing skin breakdown along the lateral surfaces of their ears (37). When prominent ears interfere with safety in such a manner, otoplasty is certainly indicated. Constricted ears, however, will often demonstrate more noticeable deformity and are not as subjective of a finding as are prominent ears. Nevertheless, they are apt to produce the same psychological concerns.

Otoplasty has traditionally been delayed until 5 years of age, at which point the ear has nearly reached its adult size, reducing concern for postoperative growth disturbance, and the child has not yet entered grade school, a time before peer ridicule becomes a significant concern. This convention has been challenged, however, and much younger patients, as young as 9 months, have undergone otoplasty without any evidence of altered cartilage growth over a course of several years. The rationale for otoplasty at an earlier age is the observation of excessive caregiver and family focus upon the ears as well as the development of self-image prior to 5 years of age (38,39). Performing otoplasty at an earlier age, however, remains controversial. In a survey of surgeons, psychologists, and parents with children who had undergone otoplasty in the United Kingdom, a majority recommended otoplasty after 6 years of age (40). Regardless, when considering otoplasty in a child, it is imperative to stress to the parents the importance of postoperative care and protective dressings. If it is unlikely that the postoperative care will be tolerated, otoplasty might be best deferred to a later time.

SURGICAL TECHNIQUES

Otoplasty for the Prominent Ear

The main goals of otoplasty for the prominent ear are to create an antihelical fold and reduce the auriculocephalic angle to about 15 to 25 degrees. In addition, a prominent, lateralized helical root and lobule can worsen with otoplasty and often require reduction as well. A wide variety of techniques have been described to achieve these goals and a selection of landmark and novel modifications is presented below, followed by our preferred technique.

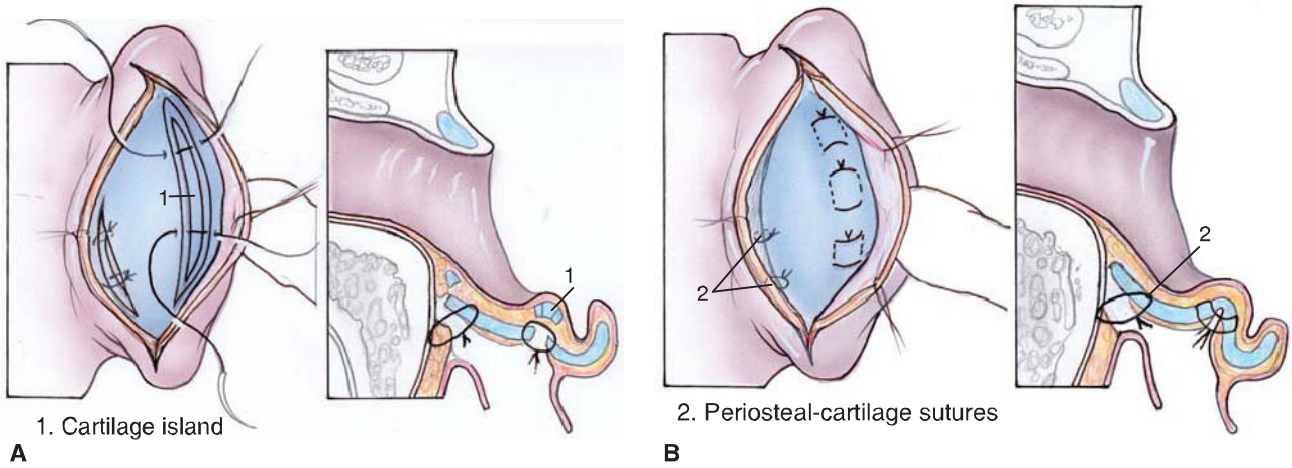

Figure 190.5 Comparison of cartilage-cutting **(A)** and cartilage-shaping **(B)** otoplasty techniques.

In 1955, Converse et al. (41) recreated the antihelical fold by making two parallel incisions on either side of the planned antihelix and suturing the edges from either side of the cartilage island together (Fig. 190.5A). In 1959, Farrior (42) described a modification of this technique, excising thin, longitudinal wedges of cartilage posteriorly at the superior crus and antihelical fold; creating a cartilage island at the planned antihelix; and stabilizing the new folds with suture. Hatch (43) noted that the helical root was often displaced laterally in otoplasty and, in 1958, reported securing the helical root to the temporalis fascia to alleviate this problem.

In 1963, Mustarde (44) described a less invasive technique of recreating the antihelical fold, using three permanent horizontal mattress sutures to secure the auricular cartilage to itself without making any cartilage incisions (Fig. 190.5B). In 1967, Kaye (45) described anterior cartilage scoring at the planned antihelical fold with toothed forceps, followed by suture fixation as well as removal of an ellipse of conchal cartilage if needed. In 1968, however, Furnas described a less invasive technique of conchal bowl reduction, simply securing the conchal cartilage to the mastoid periosteum posteriorly. The lobule was reduced by excising a posterior ellipse of skin (46). In 2001, Erol (47) described an anterior approach to otoplasty, placing their incision along the conchal bowl rim, excising a portion of conchal cartilage, scoring the anterior surface of the cartilage to create an antihelical fold, and securing these changes with horizontal mattress sutures.

Incisionless otoplasty was first described by Fritsch in 1994 and involves percutaneously scoring the anterior surface of the cartilage at the planned antihelical fold, creating a small opening at the postauricular sulcus and removing soft tissue for a conchal setback if needed, percutaneously placing horizontal mattress retention sutures from the posterior side of the pinna to create the antihelical fold and pull the concha posteriorly and burying the knots by pulling skin over them with a single-prong skin hook. The lobule is brought posteriorly by percutaneously dissecting the cauda helicis from the pinna and using the same percutaneous suture technique to secure it to the posterior conchal bowl (48).

In 1999, Epstein et al. (49) described the use of electrocautery to perform partial-thickness ablation of a thin, longitudinal strip of cartilage along its posterior surface at the planned antihelix. The new antihelix was then stabilized with horizontal mattress sutures. Ragab (50) described a modification to this technique in 2010, using the carbon dioxide laser instead of electrocautery in an attempt to curl the cartilage in a controlled fashion.

In general, these techniques fall into one of two categories: cartilage-cutting or cartilage-shaping. Cartilage-cutting techniques involve the incision or scoring of cartilage to create a permanent change to the cartilage shape. These techniques may be best suited for thick, stiff cartilage and often allow greater control over the end result. However, there is greater risk of creating sharp edges and irregularities that are extremely resistant to revision. Cartilage-shaping techniques, on the other hand, involve repositioning the cartilage with sutures to create a more natural shape without the risk of sharp, unnatural-appearing cartilage edges. The end result can easily be adjusted but carries with it the risk of a suture breaking and the ear springing back to its original position.

The surgeon must understand the risks and benefits involved with these techniques. Whenever possible, the senior author (SRM) prefers to use the cartilage-shaping techniques originally described by Mustarde, Furnas, and Hatch. The following is a detailed description of this procedure.

DESIGNING THE INCISION

Prior to injection of local anesthesia, three key landmarks must be identified.

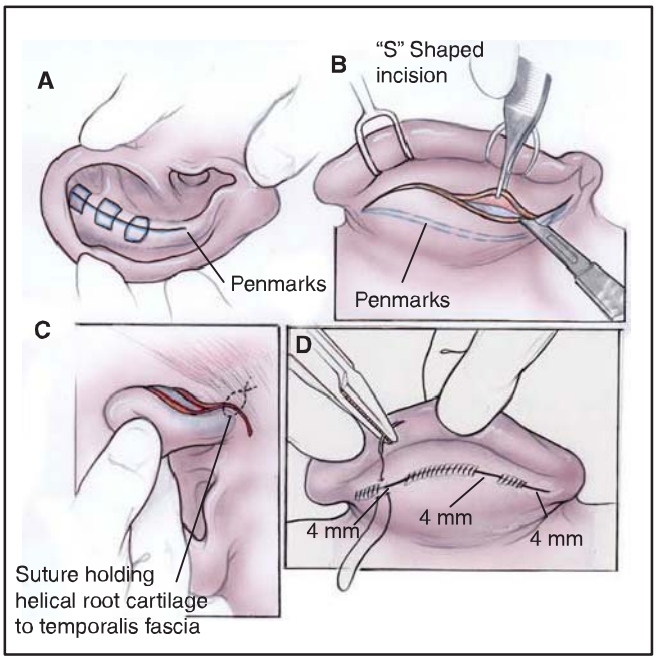

Figure 190.6 Otoplasty incision planning using Mustarde, Furnas, and Hatch techniques. First, the ear is manipulated to create an antihelical fold and Mustarde-type horizontal mattress sutures are planned **(A)**. The ear is then pushed against the scalp and an ellipse of skin that can be excised is marked **(B)**. The planned postauricular incision is extended to the helical root for repositioning to prevent persistent superior ear prominence **(C)**. When closing the postauricular incision, three 4-mm gaps are left (marked by *arrows*) as a controlled drainage pathway to prevent hematoma **(D)**. It is important that these gaps not overlie any stitches.

1. Antihelical fold: The ear should be gently squeezed to identify a naturally appearing antihelical fold (Fig. 190.6A). It is important to mark the central portion of the antihelical fold. This line should not be straight but a gentle anteriorly sloping curve that will create a more natural antihelical fold. We prefer to mark out the future placement of our Mustarde-type horizontal mattress sutures at this time.
2. Conchal setback: A cotton-tipped applicator can be used to press the conchal cartilage against the mastoid to determine where the conchal setback sutures will be placed (Fig. 190.7A and B).
3. Helical root: The placement of the helical root suture should be determined by gently pushing the helical root anteriorly and superiorly against the soft tissue of the scalp in order to determine the location of the relaxed skin tension line in this location (Fig. 190.6C).

With these three landmarks identified, one should design the postauricular incision. With a finger on the area of the future Mustarde-type horizontal mattress sutures, a small dot can be made on the back side of the ear corresponding to the location of each suture. This same technique can be used to identify where the Furnas-type conchal setback sutures will be placed. This will create two lines, which form the basis of the incision (Fig. 190.6B). These two markings can then be connected with an "S"-shaped line. Now the ear can be pressed back against the scalp and an estimation of how much excess of skin should be removed can be made and the above drawn line can then be converted to a simple ellipse. A dumbbell shape is often advocated for this incision in order to decrease the chances of developing telephone ear deformity, which is discussed later in this chapter. A simple elliptical skin excision, however, can also allow one to address the helical root and lobule and perform a straightforward closure at the end of the procedure.

Injection

Despite the common medical teaching to the contrary, there is no proven contraindication specific to the ear for injecting a local anesthetic containing epinephrine. It is important to keep in mind, however, that epinephrine injection can result in a hypertensive crisis in patients who are taking certain vasoactive medications or have underlying cardiovascular disease, uncontrolled hypertension, hyperthyroidism, or pheochromocytoma (51,52). Patients with cardiovascular disease should be injected with no more than 0.2 mg of epinephrine (20 mL of 1:100,000 epinephrine); some advocate even lower maximum doses of 0.04 mg of epinephrine (4 mL of 1:100,000 epinephrine) up to every 30 minutes in patients with severe cardiovascular disease (53,54). In comparison, doses of 0.3 to 0.5 mg of epinephrine are used for treatment of anaphylaxis.

In the senior author's experience, 1:50,000 concentrations of epinephrine can be used in otoplasty without causing damage to the skin and cartilage. With this technique, the anterior and posterior sides of the ear are each injected with 2 to 3 mL of a custom mixture of 0.25% bupivacaine with 1:50,000 epinephrine. When the procedure is performed under local anesthesia alone, it is helpful to inject 1% lidocaine with 1:50,000 epinephrine followed by 0.25% bupivacaine with 1:50,000 epinephrine after initial anesthesia has been achieved. Firm pressure should be held on the anterior and posterior surfaces of the ear after injection to minimize soft tissue distortion.

Surgical Procedure

The initial skin incision is performed with needlepoint electrocautery, which helps to minimize bleeding, decreases operative time, and results in a very acceptable scar that is well hidden in the postauricular sulcus. Once the incision is complete, the ellipse of skin is excised either sharply or with electrocautery. The converse scissors are then used to undermine the skin in the supraperichondrial plane along the superior half of the ear where the Mustarde-type horizontal mattress sutures will be placed. This dissection should be mostly avascular as long as one remains in this plane. Once this step is complete, a second round of hemostasis is performed with the electrocautery.

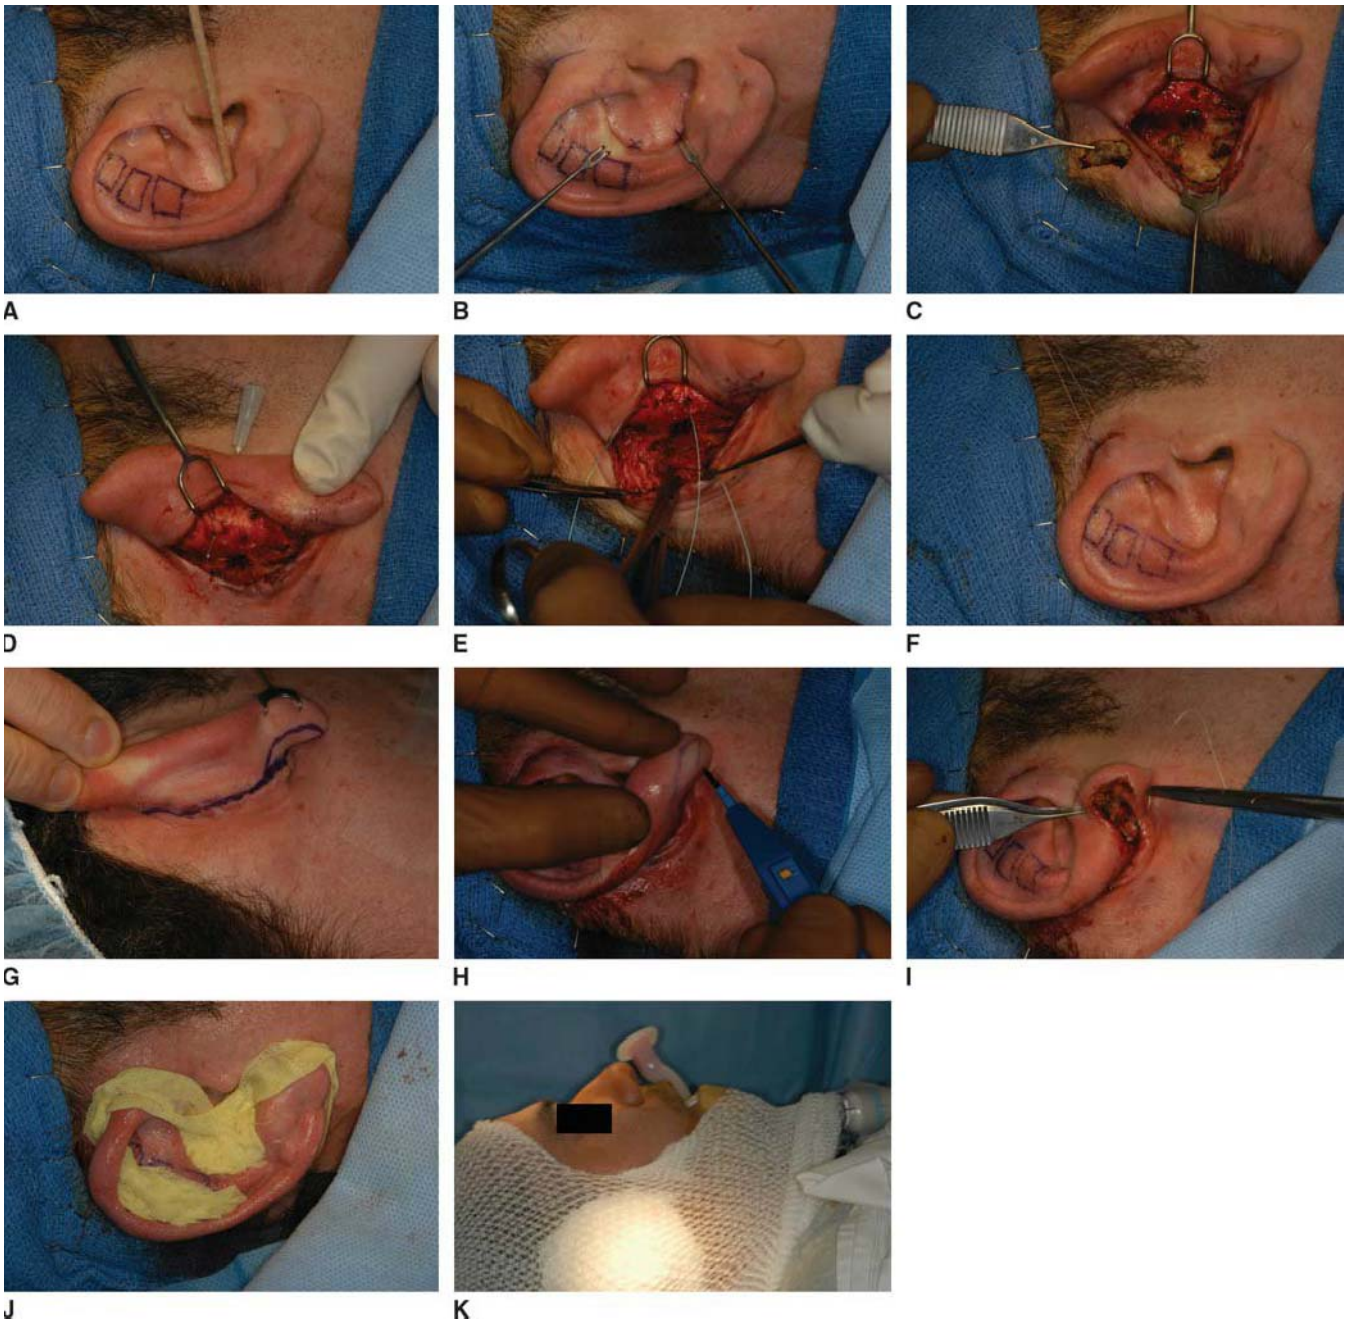

Figure 190.7 Otoplasty technique. Conchal setback sutures are planned by pushing the conchal bowl against the scalp **(A)** and marking the optimal location for suture placement **(B)**. A small amount of soft tissue overlying the mastoid is removed to allow for an appropriate conchal setback, leaving the periosteum for suture placement **(C)**. A 27-gauge needle is placed through the conchal bowl where the suture will be placed and the conchal bowl is secured to the mastoid periosteum **(D,E)**. The helical root can then be secured to temporalis fascia through an incision in a skin fold just anterior to the helical root **(F)**. The lobule can be reduced through an elliptical soft tissue excision **(G–I)**. Once complete, the ear is dressed with petrolatum gauze and wrapped with elastic net bandage **(J,K)**.

In a majority of cases, it may be easier to place Mustarde-type horizontal mattress sutures prior to Furnas-type conchal setback sutures. The reason for this is that once the conchal bowl setback sutures are placed, access to the postauricular cartilage for Mustarde suture placement may be more visually limited. However, in cases where ear prominence mostly results from a large conchal bowl, Furnas-type conchal setback sutures may be placed first without significant visual limitation. It is extremely important to modify one's technique based on each patient's unique anatomy.

Working with the surgical assistant, a repetitive set of maneuvers is then performed: A 27-gauge needle is passed

from the anterior to posterior surface in what will be a corner of the Mustarde-type horizontal mattress suture. On the back side of the ear, a cotton-tipped applicator is used to dry the cartilage, and the surgical marker is used to place a very fine dot where the needle will pierce the cartilage. This process is then repeated. In most cases, three Mustarde-type horizontal mattress sutures will be required, but two or four may be appropriate depending on the deformity. The surgeon then places Mustarde-type horizontal mattress sutures (we prefer 4-0 polyester suture), being careful to pass the needle through the full thickness of the cartilage without violating the anterior auricular skin. The initial suture is tightened to ensure that the resulting antihelix is desirable, but is then relaxed and tagged to the surrounding surgical drapes without cutting. The above process is repeated until the desired number of sutures has been placed postauricularly. The Mustarde-type horizontal mattress sutures can be tied from inferior to superior or superior to inferior depending on the case; by gently bending the pinna to create the antihelical fold, it is often evident that bending begins in one direction more naturally. Once the first Mustarde-type horizontal mattress suture is secured with a surgeon's knot, the first assistant gently pinches the edges of the newly formed antihelical fold with a penetrating towel clamp. This will allow the shape to be held in place while the operating surgeon continues to tie the sutures from the posterior side. In order to prevent the postauricular skin from catching as the suture is tied, a side-to-side "windshield wiper" motion can be performed as each knot is tied.

Preparation for Conchal Setback

Before the conchal bowl set back can be performed successfully, there must be a recipient site created into which the conchal bowl can be set. This site is created by using electrocautery to undermine a thin postauricular skin flap and remove a disc of muscle and fascia overlying the mastoid (Fig. 190.7C). It is important to leave a thin layer of tissue over the mastoid periosteum so that the conchal setback suture can be placed securely. The amount of soft tissue that is removed varies based on the amount of setback that is needed, but in general, a region of soft tissue about the diameter of a nickel or quarter and 1 to 4 mm thick should be removed.

Placement of the Furnas Sutures

Furnas-type conchal setback sutures pass through the conchal cartilage and mastoid periosteum. We begin at the conchal cartilage in a backhanded fashion such that the needle can be passed through the mastoid periosteum in a forehanded fashion, allowing better needle control for the second, more technical needle pass (Fig. 190.7D and E). Based on the cartilage rigidity and force that needs to be applied for the conchal bowl setback, the surgeon may use a combination of one or three 4-0 or 3-0 sutures. For example, in a younger patient with more elastic cartilage, two 4-0 polyester sutures are usually adequate, but in an adult patient with more calcified cartilage, two or three 3-0 polyester sutures may be indicated. It is always best to place the sutures loosely initially and tie them later, just as in creating the antihelical fold. The first assistant can hold the conchal bowl in correct position with a cotton-tipped applicator while the operating surgeon throws surgeon's knots, again with a "windshield wiper" motion.

Helical Root Positioning

An observant surgeon will notice that often after a combination of Mustarde and Furnas sutures, the helical root will almost always protrude laterally. If not corrected, this result will persist postoperatively and is the upper component of the telephone ear deformity. This area of the ear may be overlooked in cosmetic otoplasty but is as important of an area to control as the antihelical fold and the conchal setback. When needed, a helical root incision should be marked prior to the injection of local anesthetics along a natural skin crease (Fig. 190.6C). A small, 6- to 10-mm stab incision is made with a number 11 blade scalpel, and a 4-0 polyester suture is placed deep in the temporalis fascia in a forehanded fashion. The suture should be well seated such that the surgeon should feel that the head could almost be lifted off the table with the suture alone. In a backhanded motion, the suture is now passed through the inferior cartilage of the helical root and tied to bring the antihelical fold into a more natural orientation relative to the newly created antihelical fold and conchal setback (Fig. 190.7F).

Closure

Because the incision at the helical root incision could leave a perceptible scar, it should be closed meticulously with either 6-0 polypropylene or 6-0 fast-absorbing catgut suture. We have achieved good results by everting the skin edges with a few horizontal mattress sutures. As the postauricular incision is closed, three 4-mm gaps are left open to allow for the egress of blood, decreasing the risk of hematoma. The three gaps are placed 5 mm from the apex of the incision, at the midportion of the incision, and at the inferior 4 mm of the incision near the lobule. Closure can be performed in a running fashion between each gap (Fig. 190.6D).

Management of the Lobule

In cosmetic otoplasty, the lobule can sometimes be one of the more challenging structures to shape and position; this is particularly true of large, fleshy lobules that lack rigidity. When the lobule needs to be positioned closer to the scalp, which occurs approximately one-third of the time, a wedge excision can often be the simplest and most direct way to proceed (Fig. 190.7G–I). The amount of tissue that must be excised can be determined by pinching the lobule along its posterior surface. An elliptical wedge of skin should

then be marked and excised with needlepoint electrocautery. The resulting defect is closed with a 5-0 fast-absorbing catgut suture, again leaving a purposeful 4-mm gap inferiorly for the postoperative egress of blood.

Dressing

There are many different ways to dress the ear postoperatively that help to support its new shape. In one relatively simple technique, petrolatum gauze (Xeroform) is cut into five 5 mm strips, two of which are packed in the postauricular sulcus, and three of which are packed along the anterior surface of the ear. The petrolatum gauze is pressed into the peaks and valleys of the newly formed antihelix and conchal bowl (Fig. 190.7J). Following placement of the petrolatum gauze, fluffed 4 × 4-inch gauze sponges are placed over each ear and a size 8 elastic net bandage (BandNet) is placed over the face, twisted at the top, and pulled over itself to create a double layer of netting. Younger patients may be better fit with a size 7 elastic net bandage. A gap is cut through the bandage over the eyes, nose, and mouth and the inferior edge of this gap is brought over the anterior mandible like a chinstrap (Fig. 190.7K). The compression created by this dressing is designed to provide three-dimensional support to the skin envelopes overlying cartilage where several sutures have just been placed. It is essential that this pressure dressing be in place prior to extubation, especially in the case of children.

Otoplasty for the Constricted Ear

The goals of otoplasty for patients with constricted ears are to provide adequate, symmetric ear height, projection, and shape. This constellation of deformities is a much more difficult problem to correct and requires the surgeon to be facile in multiple techniques of otoplasty and auricular reconstruction. Several of these techniques for management of the constricted ear will be presented in this section, however, further detail, especially pertaining to rib graft harvest, is beyond the scope of this chapter.

Mild Constricted Ear

Mildly constricted ears, as stated above, can be treated with molding techniques in neonates or even in some older individuals. However, molding is dependent upon cartilage elasticity. Surgically, these patients are often candidates for otoplasty similar to that performed for prominent ears. If standard otoplasty techniques are to be employed, it is critical that the cupped superior helix is able to be manually unfurled into a nearly normal shape. If this manipulation can be performed but requires a significant amount of force, transcutaneous placement of through-and-through 4-0 silk sutures to create the antihelix and reduce helical prominence can be useful in determining if they alone can hold the ear in position for several days to a week preoperatively. If the desired shape can be appropriately retained over this period of time, a standard otoplasty technique using Mustarde-type horizontal mattress sutures similar to the procedure described above can be used (Fig. 190.8). If sutures are unable to hold the ear in place, however, cartilage-cutting techniques may be required.

Moderate and Severe Constricted Ear

Moderately constricted ears are often difficult to separate from patients who are more appropriately in the mildly or severely constricted categories. Often they will require a V-Y advancement of the helical root to release the helical rim into a more natural position and may require cartilage grafting (Fig. 190.9) (25).

The severely constricted ear, on the other hand, always requires cartilage grafting and often requires an adjacent tissue transfer or skin graft. The most useful cartilage for auricular reconstruction is from the rib. In the constricted ear, partial shaved rib cartilage can be easily harvested with minimal donor-site morbidity. Shaved cartilage will also curl to create a contour very amenable to superior helical reconstruction (Fig. 190.10).

Complications

Fortunately, complications after otoplasty are rare, but they do occur and can in some cases be quite severe. Early complications include infection, chondritis, hematoma, pain, and skin necrosis. Infection and chondritis are the most devastating as they can lead to loss of cartilage and require multiple reconstructive procedures. Generally, a patient developing infection will experience worsening pain around the third or fourth postoperative day, followed by swelling and drainage from the ear. Once infection is suspected, any fluid collections should be drained, a culture should be obtained if possible, and the patient should be treated aggressively with antibiotics. The patient may at first be given oral antibiotics, but if no response is noted within 48 to 72 hours or the infection appears particularly aggressive, broad-spectrum intravenous antibiotics covering skin flora as well as potential pseudomonal infection should be initiated. Hematoma is often a result of either inadequate hemostasis at the time of surgery or postoperative trauma and is suggested by sudden swelling at the surgical site. If detected, a hematoma should be drained expeditiously to prevent infection, calcification, and cartilage loss. Purposeful gaps in closing the postauricular incision can help to prevent this complication if excessive bleeding were to occur. Pain that worsens more than expected in the postoperative period may signal any of the aforementioned complications as well as possible hypersensitivity reactions to the dressing or excessive tightness of the dressing. Skin necrosis is a very rare complication in otoplasty that may be more common in individuals with poor peripheral circulation, such as smokers or diabetics, but may also be caused by excessive dressing tightness (55–58).

Late complications after otoplasty include inadequate correction, telephone ear deformity, abnormal ear

Figure 190.8 Mild to moderately constricted ear. In this 16-year-old with a mild to moderately constricted ear, the ear could be unfurled, but with a significant amount of force **(A–C)**. Because the patient was older and able to tolerate an office procedure, through-and-through 4-0 silk sutures were placed transcutaneously to ascertain if they alone would hold the ear in the correct position **(G)**. If these sutures had failed, the next treatment option would have been an auricular reconstruction with a partial shaved rib graft. The sutures were placed approximately 1 week preoperatively and held the ear in position. Intraoperatively, a postauricular incision was created, and several, strong Mustarde-type sutures were placed along the superior helix. This patient had a satisfactory result at the 6-week postoperative appointment and ultimately did not require a rib graft as the ear height result was a close enough match to the opposite side that the patient did not feel further surgical intervention was warranted **(D–F)**. This suturing technique allowed for better preoperative decision making and demonstrates the difficulty that can be encountered when deciding on a treatment strategy for patients with constricted ears.

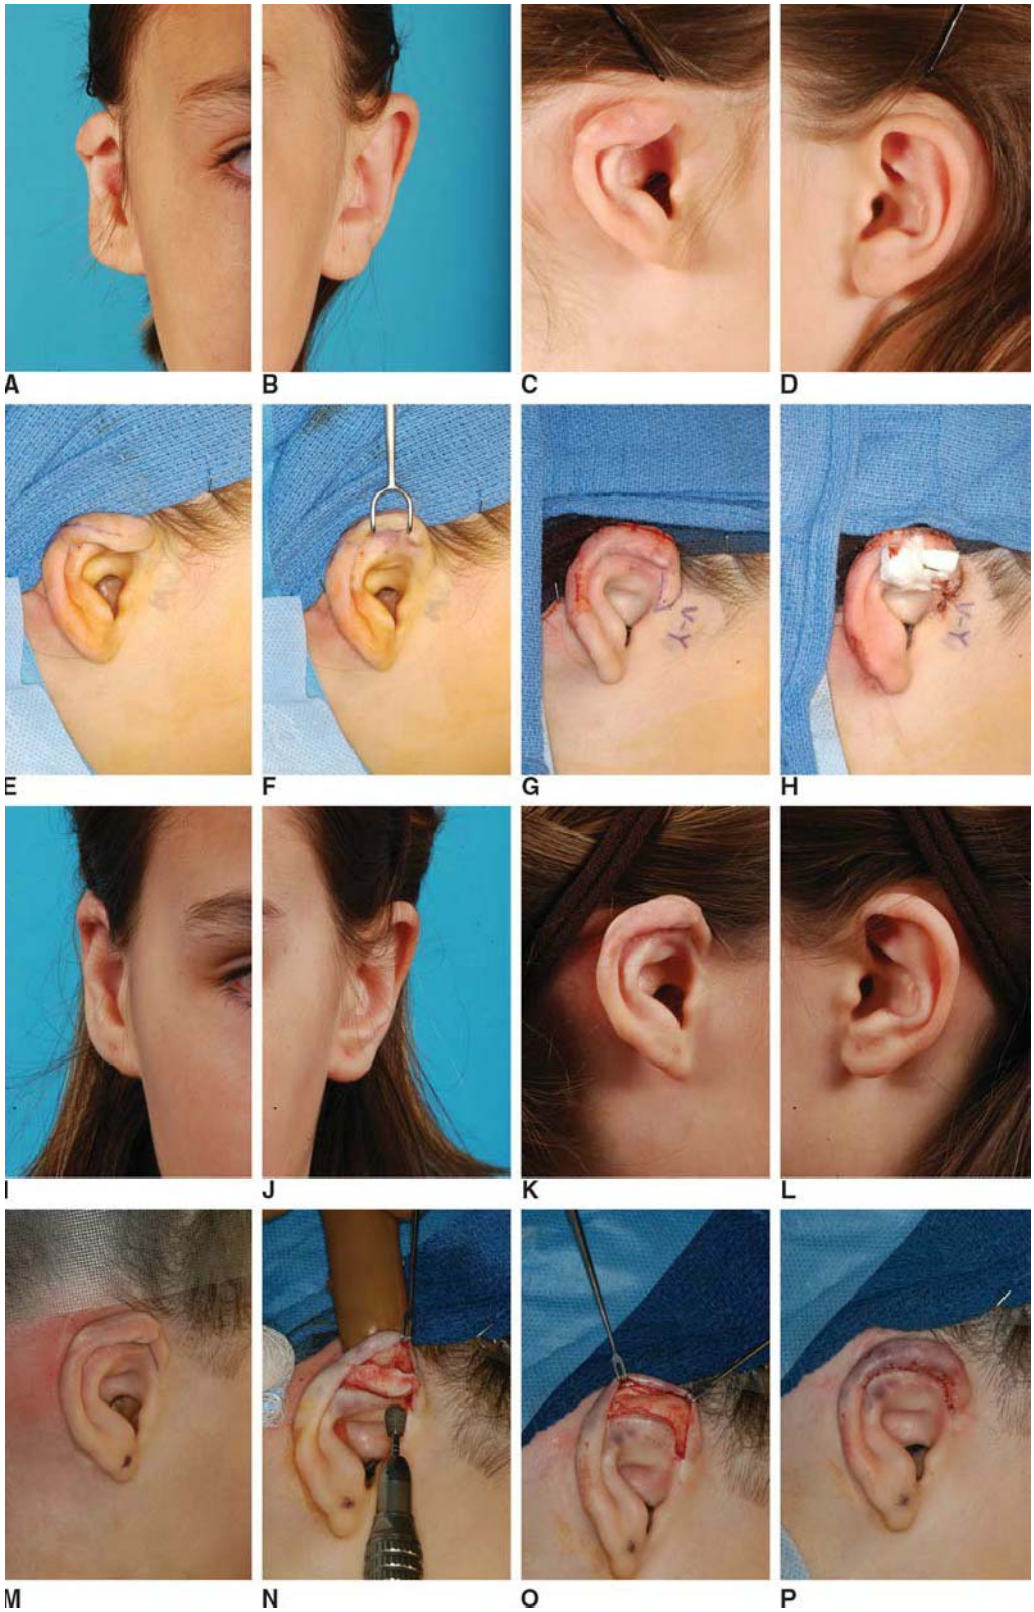

Figure 190.9 Moderately constricted ear. This 7-year-old presented with a constricted upper one-third of the ear that had been attempted to be repaired using standard otoplasty-type techniques twice without success **(A–D)**. The ear was able to be nearly completely unfurled, but was excessively cupped and seemed to be held in place at the helical root **(E,F)**. In addition, the ear had an irregular appearance, and plans were made for a two-stage procedure: the first to correct the height and shape and the second to remove the ear's contour irregularities. In the first stage, an incision was created just posterior to the helical rim along the upper one-third. The cartilage in this region was degloved along its anterior and posterior surfaces, providing broad exposure and allowing the placement of standard Mustarde-type horizontal mattress 4-0 polyester sutures to unfurl the ear. Once unfurled, the skin was brought back over the cartilaginous structure of the ear and a V-Y release of the helical root was performed, allowing the ear to achieve greater vertical height **(G,H)**. A standard bolster dressing was applied because of the wide undermining that was required. About 1 year later, the second-stage surgery was performed to improve the irregular contour of the cartilage. This delay allowed us to ensure that the ear was completely healed and had achieved adequate vertical height correction **(I–L)**. The cartilage was, again, widely degloved, and a diamond-tipped dermabrader was used to correct contour irregularities **(M–O)**. A 1 × 4 cm thick piece of AlloDerm was then evenly spread over the entire upper one-third of cartilage to provide a soft tissue cushion to the overlying skin **(P)**. A bolster dressing was again placed because of wide skin undermining.

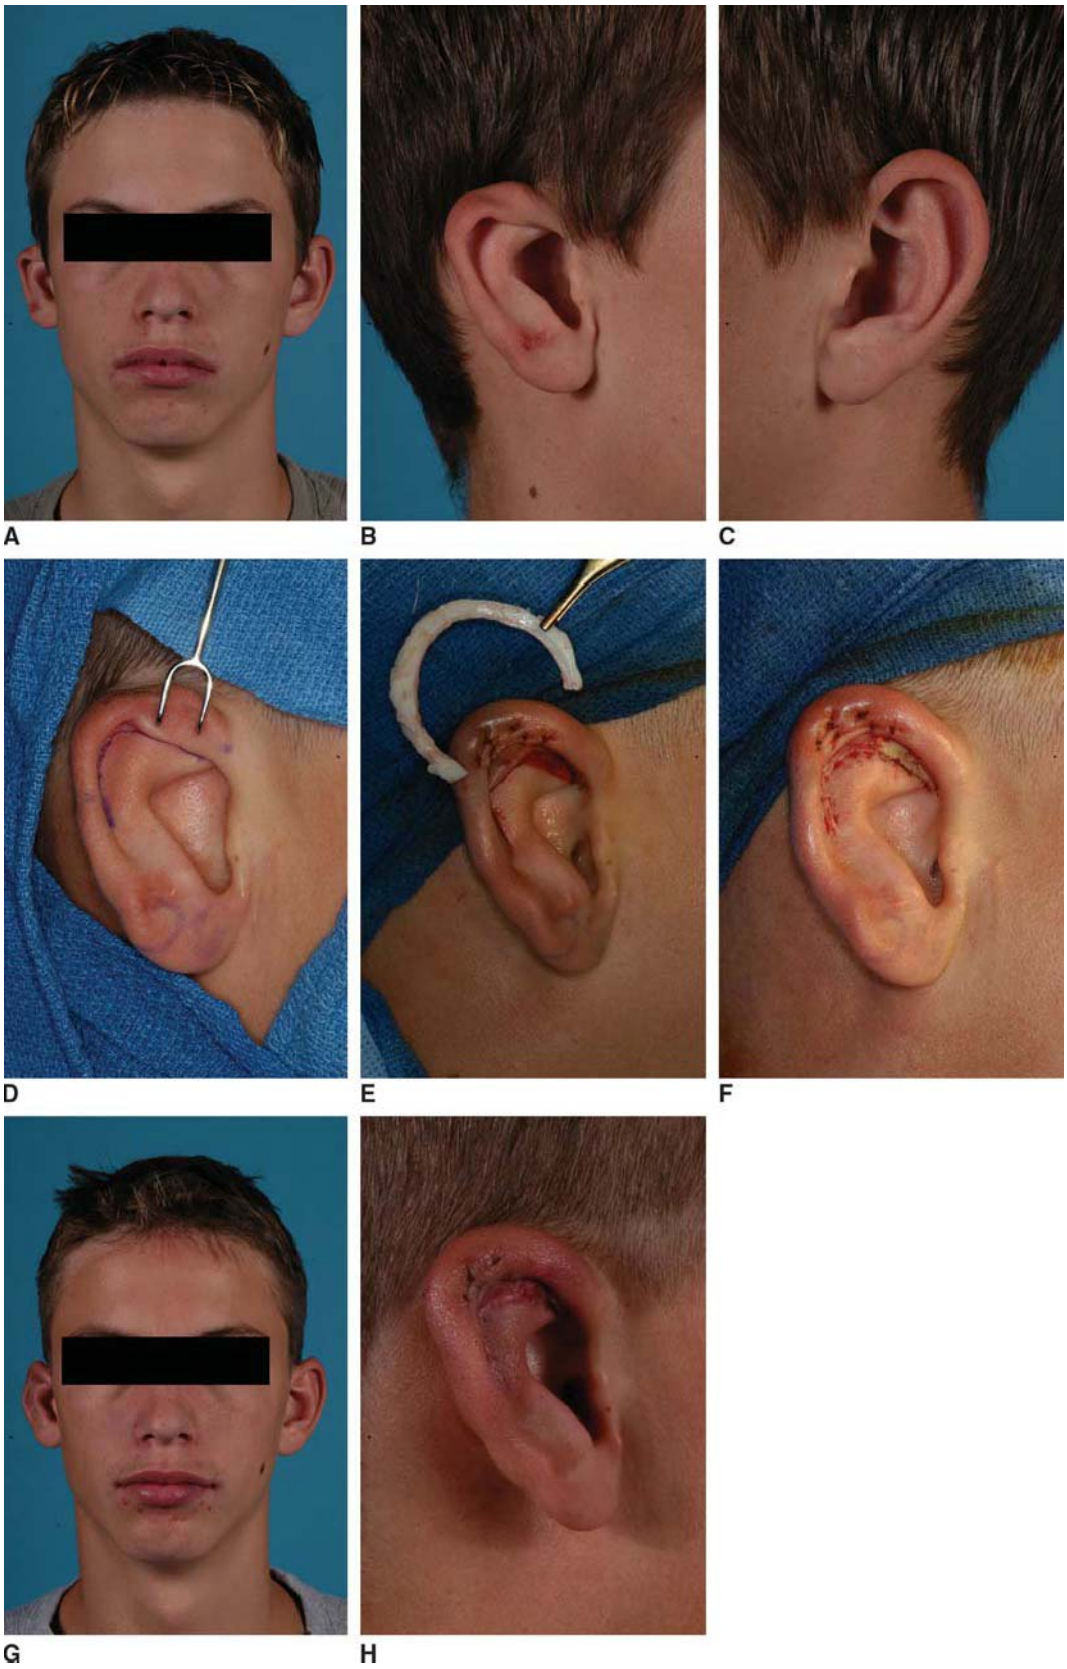

Figure 190.10 Moderate to severely constricted ear. The following 17-year-old had a moderate to severely constricted upper one-third of the ear that would not unfold in the office **(A–C)**. The patient was taken to the operating room shortly thereafter for a rib graft to obtain adequate ear height and stability. First, the anterior portion of the helix was incised to allow the ear to release. A template was made of the contralateral ear using sterilized x-ray film, similar to a standard microtia repair, in order to determine the goal for ear height. Next, 5-cm-long, 2- to 3-mm-wide partial-thickness rib graft was harvested, leaving a majority of the rib in the patient's chest, a technique that significantly decreases postoperative pain. The rib was then placed in normal saline while a standard closure of the chest incision was performed and the ear was unfurled. A soft tissue pocket was then created near the root of the helix to the midbody of the helical rim. The rib was then placed in this soft tissue pocket and held in place with through-and-through sutures **(D,E)**. Once the ear was completely unfurled and the vertical height of the contralateral ear matched, the anterior auricular skin defect where the ear had been unfurled was measured and a postauricular skin graft harvested for coverage and secured in place **(F)**. In the end, a reasonable ear was obtained and the patient was pleased with the result **(G,H)**.

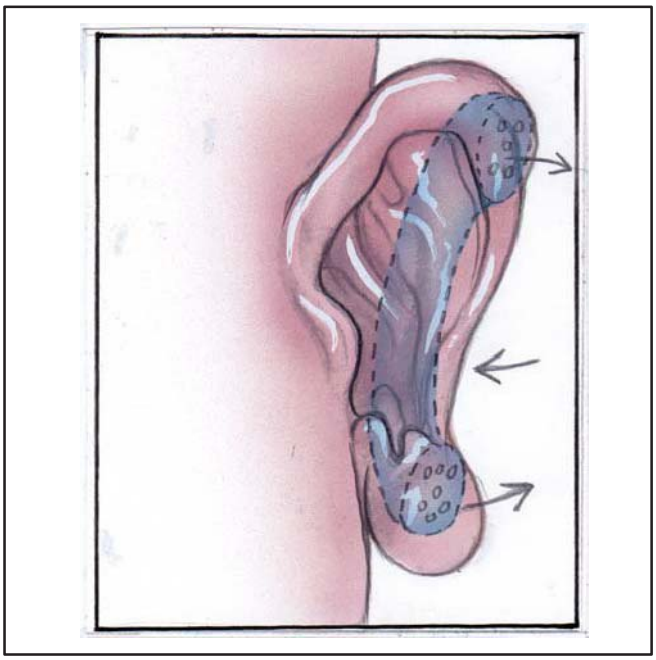

Figure 190.11 Telephone ear deformity is a postoperative result of adequate correction of ear projection in the middle one-third, but inadequate correction of ear projection in the superior and inferior one-third.

contours, keloids, suture granulomas, and extruded or broken sutures. The most common of all complications is inadequate correction of the deformity, often related to the antihelical fold or conchal setback. This problem can be addressed through revision surgery. Telephone ear deformity can be thought of as a type of inadequate correction. This problem is caused by a failure to address a laterally protruding helical root and lobule, both of which are accentuated by the creation of an antihelical fold and conchal setback (Fig. 190.11). This constellation of findings gives the ear a telephone-shaped appearance and can be addressed through revision surgery. Telephone ear deformity can be prevented by the astute surgeon by performing a helical root setback and lobule reduction at the time of initial surgery. Abnormal ear contours may result from cartilage-cutting techniques in which sharp cartilage edges can result. Revision surgery may be required to smoothen these contours. Keloids may form after otoplasty, especially in darker skinned individuals who are prone to them. Keloids can be treated with triamcinolone injection as in any other location. Suture granulomas can occur at any time postoperatively and are often noticed as a subcutaneous lump. These granulomas are treated by incising the skin and removing the suture underneath. Finally, cartilage-shaping techniques are most susceptible to sutures breaking and the ear springing back to its original position (Fig. 190.12). These sutures may also extrude and need to be removed without breaking. Revision surgery may be required in these cases as well (55–58).

LONG-TERM RESULTS

In general, the anatomic results and patient satisfaction for otoplasty are excellent (Figs. 190.13 and 190.14). Some of the immediate postoperative medialization is expected to be lost over time and seems to occur to a greater degree in cartilage-shaping techniques. Messner and Crysdale, using a cartilage-shaping technique similar to the technique described in this chapter, found that 0.9 to 5.8 mm of medialization was lost 1 year after surgery with the greatest amount of loss along the middle and superior thirds of the ear. Overall, 29% of ears returned to their preoperative positions, 28% of ears remained in their immediate postoperative positions, and 43% of ears were found

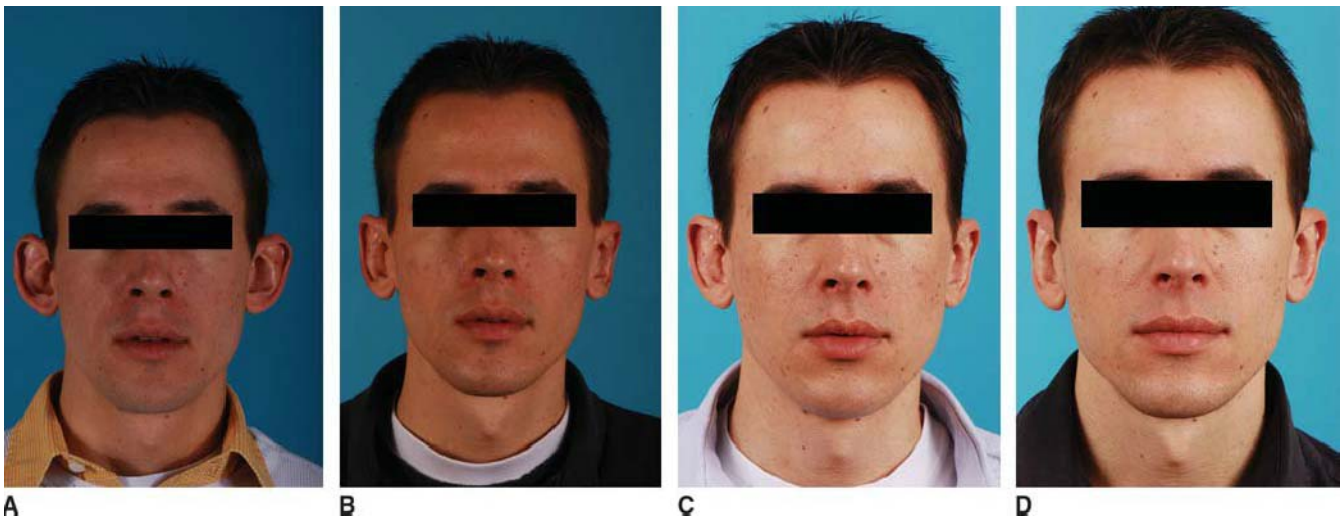

Figure 190.12 Example of suture breaking after otoplasty. **A:** Preoperative image of patient with prominent ears. **B:** Initial postoperative ear projection. **C:** Ear projection after Mustarde-type horizontal mattress suture failure at right ear. **D:** Ear projection 1 year after revision surgery for suture failure.

to lie somewhere in between. Despite a 29% return to preoperative position, 85% of patients and their families were happy with the results, but only 73% would choose to undergo otoplasty again (59). Schlegel-Wagner et al., using an anterior cartilage-scoring technique with posterior suture fixation, found that 2 mm of medialization was lost by 6 years postoperatively, with the majority of recurrence along the superior third of the ear. Overall, 90% of patients and families reported either a "good" or "very good" result (60). Using a cartilage-cutting technique that involves removing a diamond-shaped section of cartilage and suturing it into a tube to create a new antihelix, Lee and Bluestone (61) found that all patients and their families were either "very satisfied" or "extremely satisfied" with the results at 4.6 years postoperatively; however, no measurements were provided.

CONCLUSION

In treating a patient with an anomalous ear, one must consider several factors. Adequate counseling and understanding patient expectations and psychosocial concerns are paramount to patient and family satisfaction. Molding techniques should certainly be considered in newborns with ear deformities but are more controversial in older children. Laser-assisted cartilage reshaping may significantly increase molding success rates, especially in older children and adults, and become a preferred method of treatment in the future. If molding techniques do not adequately correct the deformity or if a child has a mild to moderate malformation, the otoplasty techniques discussed in this chapter may be appropriate. Otoplasty has traditionally been performed after 5 years of age, but this timing has been challenged and otoplasty potentially may be performed at an earlier age. There are a number of otoplasty techniques

that have been devised, broadly categorized as cartilage-cutting or cartilage-shaping, and the surgeon should be aware of the pros and cons of these techniques in order to adequately counsel patients preoperatively. Some degree of postoperative lateralization is likely to develop over time, and although the most common complication of otoplasty is inadequate correction, patients and their families can generally expect to be satisfied by the result. Thorough knowledge of auricular anatomy and tailoring surgical technique to each individual ear can help to achieve better, longer-lasting results.

HIGHLIGHTS

- The external ear develops from six hillocks of His that are derived from first and second branchial arch mesoderm.
- The ear reaches 85% of its adult size by 3 years of age and nearly its full adult size by 5 years of age.
- Prominent ears are characterized by an absent antihelical fold and large conchal bowl.
- There is no absolute definition of prominent ear; an ear is prominent when a patient says it is.
- Constricted ears are characterized by a purse-string appearance caused by a lack of cartilage at the upper one-third of the helix and sometimes concha.
- Auricular anomalies may impact psychosocial development.
- Ear molding techniques are most effective in neonates less than 3 weeks old and lose effectiveness with age and increasing cartilage rigidity.
- Most otoplasty surgical techniques can be broadly categorized as either cartilage-cutting or cartilage-shaping.
- Inadequate correction is the most common complication of otoplasty.
- Telephone ear results from failure to address a laterally prominent helical root and lobule.

Congenital Auricular Malformation

191

Eugenio A. Aguilar III *Anthony Echo*

Correction of auricular malformations requires a comprehensive knowledge base of the existing surgical procedures. Surgery, without the knowledge in selecting the proper technique, will cause great harm. As with any surgical operation, successful outcome depends foremost on the surgeon's experience and meticulous attention to detail in both planning and execution. In addition, the plastic surgeon should realize that the care of the patient with an ear deformity may necessitate a team approach that includes an otologist, audiologist, radiologist, and psychiatrist. The family should be an integral part of the surgical planning at the outset. This chapter covers ear deformities ranging from simple protruding ears to major congenital deformities.

ANATOMY AND EMBRYOLOGY

Topographic landmarks in a normal ear are shown in Figure 191.1. Of particular importance are the helix, superior crus, inferior crus, scapha, and antihelix as well as the cymba conchae and the cavum conchae, the two structures that make up the entire conchal bowl.

The development of the auricle is first seen in the 5-week-old embryo. The auricle begins as six mesenchymal proliferations at the dorsal ends of the first and second pharyngeal arches surrounding the first pharyngeal cleft. Initially, the external ear is located in the lower neck. As the mandible develops, the ear ascends to the side of the head at the level of the eyes. The current theory behind auricular development (Fig. 191.2) is that the six hillocks correlate directly with the tragus, helix, cymbum, scapha, antihelix, and antitragus (1).

The ear is made of both intrinsic and extrinsic musculature. The intrinsic muscles are the major and minor helixes, the tragus, the antitragus, the transverse, and the oblique. The extrinsic muscles include the anterior auricularis, superior auricularis, and posterior auricularis.

The auricle receives its blood supply from three arteries: the superficial temporal, the posterior auricular, and the occipital. The venous system involves the posterior auricular, external jugular, superficial temporal, and retromandibular veins. The lymphatic system of the ear drains anteriorly to the parotid lymph nodes and posteriorly to the cervical lymph nodes. Cranial nerve VII supplies the motor innervation of the auricle, with the temporal branch supplying the anterior and superior auricularis muscles and the posterior auricular branch supplying the posterior auricularis muscles. The sensory innervation is supplied primarily by the lesser occipital nerve, the mastoid branch of the lesser occipital nerve, the great auricular nerve (C2, C3), and the auriculotemporal nerve. Arnold nerve, a branch of cranial nerve X, supplies the concha.

A normal auricle and its dimensions are shown in Figure 191.3. The superior aspect of the ear is usually level with the eyebrow (2). The vertical axis of the auricle is typically inclined approximately 20 degrees posteriorly. The vertical height is usually equal to the distance between the lateral orbital rim and the root of the helix at the level of the brow (about 6 cm), and the width is approximately 55% of the length. The helical rim protrudes 1 to 2 cm from the skull at a 21- to 30-degree angle. Traditionally, an ear is considered deformed when the dimensions deviate significantly from these general rules. However, aesthetic appeal is often both subjective and culturally specific. Meticulous preoperative planning with special attention to these factors is essential in achieving normal-appearing and aesthetically pleasing ears.

PROTRUDING EARS

Protruding or prominent ears are a fairly common defect. An extensive array of surgical options is available, and every plastic surgeon should know at least one technique that can be used to achieve reliable results. Optimal

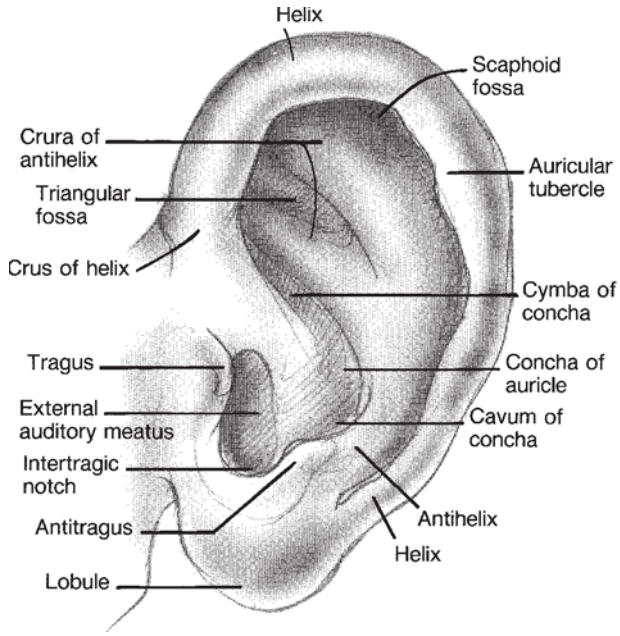

Figure 191.1 Anatomy of the auricle.

surgical outcome depends on a combination of artistic and technical skills. Although the diagnosis of protruding ears is often made by sight, knowing the basic anatomical dimensions will ensure appropriate decisions regarding intervention. The normal angle between the ear and the head should be between 20 and 25 degrees (3). Usually, an angle greater than 30 degrees makes the ears appear overly noticeable. Sometimes the auriculocephalic angle of the ear is less than 30 degrees, but some particular anatomic feature makes the ear offensive to the family or patient; therefore, a thorough preoperative assessment and discussion are necessary.

A prominent ear deformity is usually associated with a poorly formed antihelical fold and an overdeveloped concha. The scapha may be malformed with deficient superior and inferior crura surrounding the fossa triangularis. In addition, the helix may be abnormal in both definition and curvature.

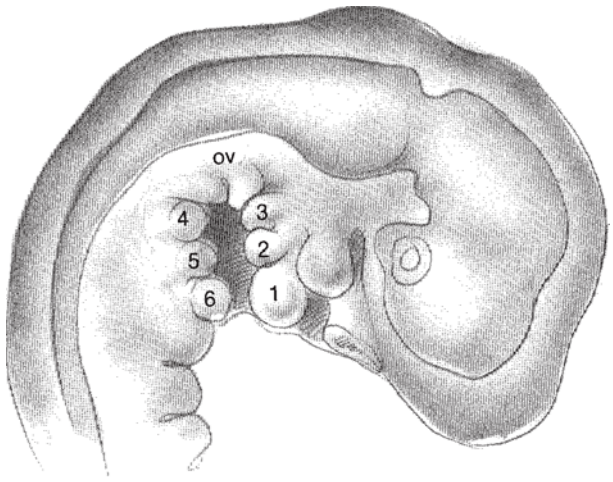

Figure 191.2 Auricle in 5-week human embryo develops from six hillocks.

Preoperative Evaluation

The preoperative evaluation should include good photographs. In addition to the frontal view, adequate documentation should include oblique, lateral, and rear views. Both ears should be compared and evaluated with regard to at least three basic criteria: the thickness and stiffness of the cartilage and the symmetry of one ear compared with the other. Darwinian tubercles should be noted, as should any other preauricular tags that may exist.

A checklist such as that in Table 191.1 will ensure that no important details are missed in the preoperative evaluation. This information should be discussed fully with the patient and family to clarify any points of uncertainty. The more involved the patient is in the planning of the surgical procedure, the more likely the postoperative care will be implemented properly.

Emphasizing the importance of making ear reconstruction a family affair, Eavey (4) counsels parents about the condition as well as techniques to correct the ear. In his study of 92 pediatric patients, Eavey (4) observed that children with microtia and significant auricular malformation require global attention to early family guidance, including expected and unexpected hearing loss, delayed language development, associated medical conditions, and the need for both auricular and otologic reconstruction.

In 1999, Wang (5) advocated that early prosthetic treatment is psychologically beneficial to children with congenital ear deformities. In addition, he described procedures to determine precise locations of craniofacial auricular implants by using computed tomographic (CT) scans. Although CT scan is not typically necessary for the correction of prominent ear deformities, it is a useful tool for more complex congenital deformities.

The usual goal of the operation is to achieve some reduction of the auricle angle to within 15 to 25 degrees while maintaining normal appearance and curvature of the auricular components. The helical curve should remain gentle following surgery, with no unusual breaks or pinching effects. The helical rim should be evaluated after the surgery and its height from the mastoid skin documented. The middle third of the helix should measure 14 to 16 mm and the superior third 16 to 18 mm. Reduction of the overdeveloped conchal bowl may be necessary during the surgery as well.

Otoplasty is best begun before the child starts school, between ages 5 and 6, when the child is old enough to withstand the necessary postoperative manipulations. However, Gosain (6,7) has demonstrated that it is safe to perform otoplasty on children as young as 9 months old without any effect on the development of the ear.

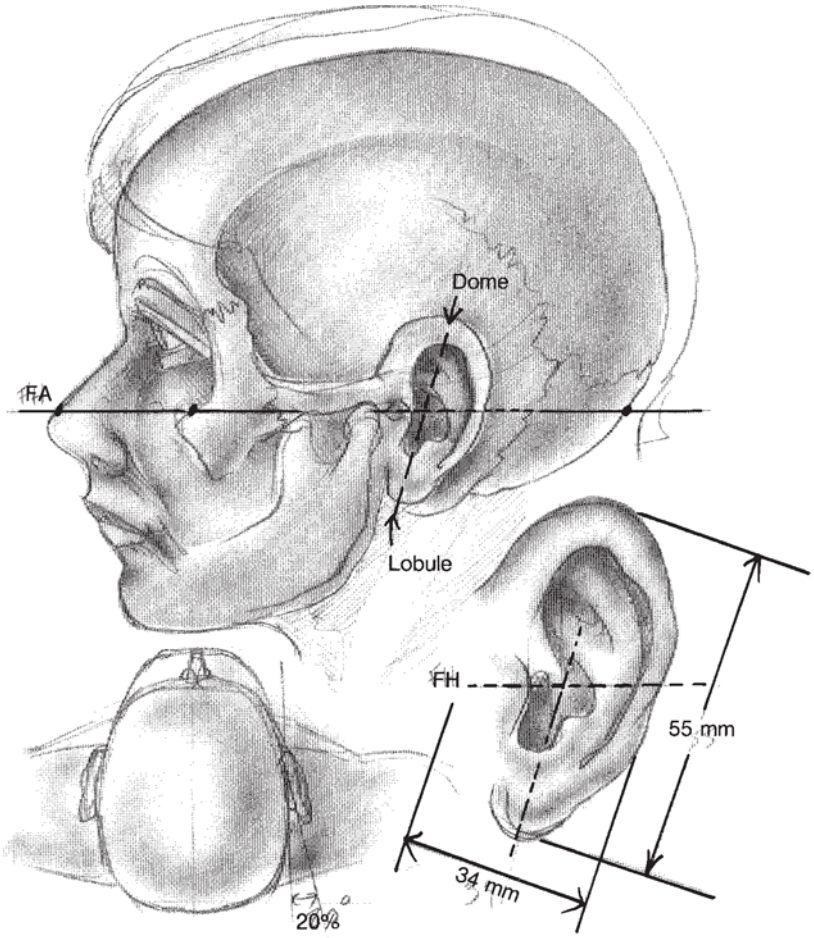

Figure 191.3 Normal ear, with average dimensions for a 6-year-old child.

Surgical Techniques

Mustarde Technique

The Mustardé technique (Fig. 191.4) involves placing several horizontal mattress sutures (usually Ethibon or Ticron) along the scapha in a curved line to create an antihelical sulcus. This technique has several advantages. A normal-appearing antihelical fold can be created, and when placed correctly, the sutures hold indefinitely. Most surgeons tend to forget that a Mustardé suture also can be used to create a more than adequate superior or inferior crus.

Problems can be expected with this technique if the sutures are incorrectly placed since they could become noticeable or erode through the postauricular skin. For this reason, postauricular skin excision is usually not recommended. Furthermore, to improve the placement of the sutures, Brent (8) recently described a hydrodissection technique where normal saline is injected on the anterolateral surface of the ear to elevate the skin away from the cartilage to allow a full-thickness bite of the perichondrium and cartilage. Should the sutures fail to maintain the proper curve of the antihelical fold, a second operation may be required. Simply using a Mustardé technique is usually not sufficient enough for most otoplasties, because work must be done in the conchal bowl area as well.

Converse Technique

The Converse technique (Fig. 191.5) is more complicated and should be executed only by an experienced surgeon (3). With this technique, an island of cartilage is created that sits anteriorly to the rest of the conchal cartilage. This cartilage produces a normal-appearing fold, with no sharp edges on the corrected antihelix. The advantages of this technique are that it allows more permanent retraction of the auricle and is a potentially more permanent correction of the antihelix. In addition, because the island itself is not sutured, the curvature of the newly created antihelix is gentle.

Farrior Technique

This technique (Fig. 191.6) also requires an experienced surgeon (9). The incisions are made through the cartilage on the conchal rim only; then longitudinal wedges are removed at the level of the superior crus and the future antihelical fold. An incision then is made through the cartilage at the level of the antihelical fold, creating an island similar to that of the Converse technique. The island widens from the inferior to the superior. This technique produces a more gentle bend of the antihelix. Recent literature has shown that there is approximately a 12% recurrence rate with this technique (10).

TABLE 191.1 DIAGNOSIS OTOPLASTY

Deformity criteria
Angle between ear and head 25° to 30° or greater
Dimensions different from normal auricle
Vertical axis—about 20° posteriorly
Vertical height—about 6 cm
Width—about 55% of length
Helical rim—1- to 2-cm protrusion from skull
Angle protrusion—21° to 30°
Superior aspect—usually level with brow
Other anatomy that makes ear offensive to family or patient
One or more significant auricular landmarks of deformity
Very poor antihelical fold
Overdeveloped concha
Abnormally formed scapha
Obvious lack of superior and inferior crus surrounding fossa triangularis

Comparative criteria
Thickness of scaphal cartilage
Stiffness of scaphal cartilage
Symmetry of two ears
Darwinian tubercles
Other preauricular tags

Documentary photographs
Frontal view
Oblique view
Rear view

Pitanguy Technique

The Pitanguy technique (Fig. 191.7) uses a smaller island flap and a conchal setback suture (3). It is appropriate for use with patients who have only a small amount of antihelical cartilage. Again, this technique requires an experienced surgeon and carries a recurrence rate of 4% (11).

Furnas Technique

The Furnas conchalmastoid suture technique (Fig. 191.8) is an important procedure for reducing a conchal bowl, as part of any successful otoplasty procedure. When the conchal bowl is too large, an island can be excised to narrow the dimensions of the bowl and to allow the proximal portion to lie firmly against the mastoid bone. The Furnas technique should always be used in conjunction with a conchal-reducing technique. This technique helps to retract the auricle permanently. If the suture is placed too far anteriorly on the mastoid, it can cause some forward buckling of the conchal bowl at the os of the external canal, leading to partial closure of the canal. To avoid narrowing the external auditory canal, it is important to remember to place the mastoid end of the conchalmastoid suture as far posteriorly as possible. These five otoplasty techniques are summarized in Table 191.2.

Complications and Emergencies

Four major complications can occur following otoplasty (Table 191.3). The most common complication is inadequate correction, and patients and their families should be alerted to this possibility prior to the operation. A secondary operation may be required within a year, even when the initial otoplasty has been performed by a well-trained surgeon.

A hematoma is probably the easiest problem to detect and is often revealed during the first postoperative examination. Simple drainage should treat this complication. Another complication is the "telephone ear" deformity, which is caused by too much flexion of the antihelix at a level equal to the midportion of the ear and inadequate flexion at the superior and inferior poles. This problem can be prevented by repeatedly checking the tension on all sutures during surgery. Reverse telephone ear can occur from overzealous tightening of the superior and inferior third of the ear.

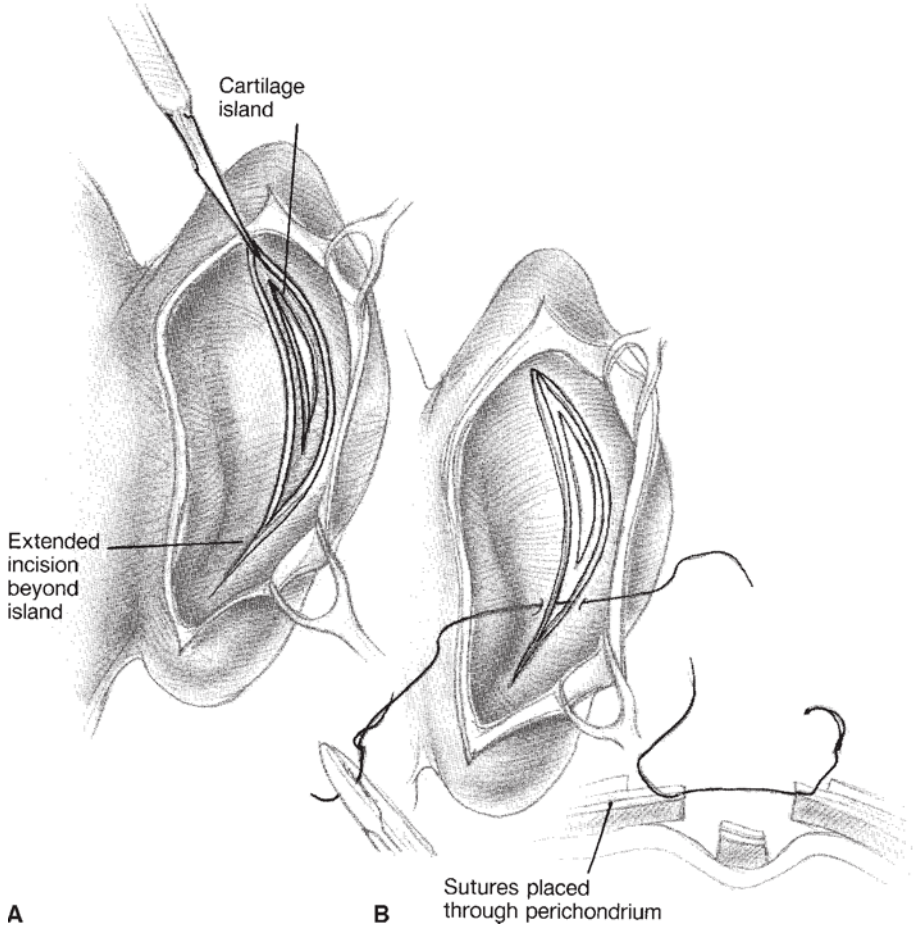

Figure 191.7 Technique of Pitanguy. **A:** Postauricular incision and creation of antihelical island flap. **B:** Conchal reduction sutures and sutures around island flap.

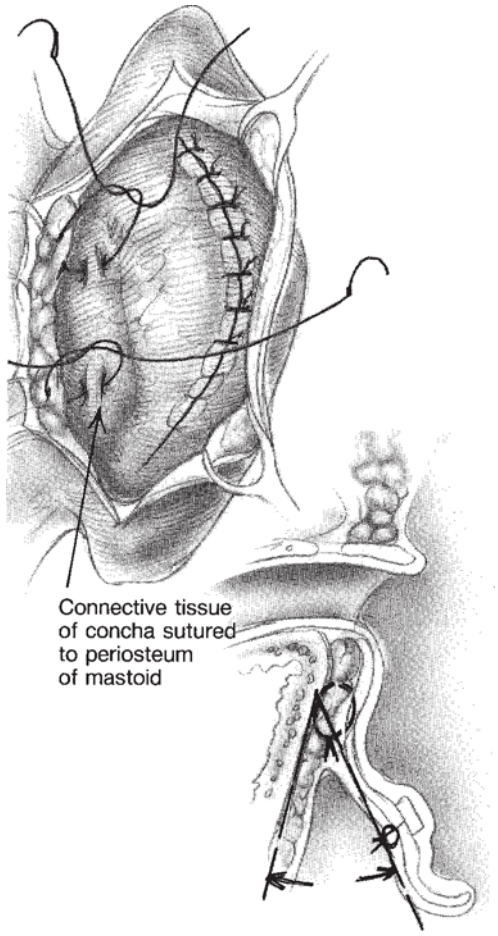

Figure 191.8 Conchal mastoid suture of Furnas.

The most feared complication of otoplasty is chondritis. Infection of the cartilage after an otoplasty can cause permanent, devastating changes in the anatomy of the auricle for which no viable solution exists. Therefore, any infection should be treated promptly and aggressively with antibiotics and possible incision and drainage.

Clinical Indicators for Plastic Repair of the External Ear

Strategy
- Indicators (one of the following)
  - Congenital or traumatic amputation, defect, or deformity
  - Reconstruction following resection of benign or malignant tumor
- Laboratory tests (as indicated)
- Other tests (as indicated)
- Type of anesthesia (as indicated)
- Location of service (as indicated)

Process
- Criteria for discharge
  - Recovery from anesthesia
  - No bleeding
  - Outcome

Results
- Adequacy of resection margin
- Treatment plan for malignant disease if found

Follow-up
- Wound healing
- Cosmetic result
- Evidence of recurrence
- Counseling of patient regarding disease process

TABLE 191.2 TREATMENT OTOPLASTY

Mustardé technique
- Advantages
  - Very normal-appearing antihelical fold can be created, which sutures can hold indefinitely.
  - Sutures also can be used to create good superior or inferior crus.
  - Inexperienced surgeons can use this technique successfully.
- Disadvantages
  - Incorrectly placed sutures will cause problems.
  - Technique is not applicable for work in conchal bowl area.

Converse technique
- Advantages
  - Island of cartilage with normal-appearing fold can be created.
  - More permanent retraction of auricle is facilitated.
  - Gently curved and potentially more permanent correction of antihelix is permitted.
- Disadvantage
  - Experienced surgeon must perform.

Farrior technique
- Advantage
  - Bend of antihelix is gentle.
- Disadvantage
  - Experienced surgeon must perform.

Pitanguy technique
- Advantage
  - Patient can have small amount of antihelical cartilage.
- Disadvantage
  - Experienced surgeon must perform.

Furna conchal mastoid suture technique
- Advantage
  - Permanent retraction of auricle is facilitated.
- Disadvantage
  - Partial closure of os of external canal occurs.

TABLE 191.3 POTENTIAL COMPLICATIONS AND EMERGENCIES OTOPLASTY

Complications
- Chondritis (most feared)
- Inadequate correction (most common)
- Hematoma (easiest to detect)

Emergencies
- Acute infection
- Hematoma

The American Academy of Otolaryngology–Head and Neck Surgery and the American Society for Head and Neck Surgery have published clinical indicators for surgical procedures. These clinical indicators are educational statements that have been drafted to assist surgeons in their practice and to promote discussion. These indicators are not practice guidelines nor do they represent standards of practice with which individuals must conform.

CONGENITAL MALFORMATIONS

Congenital malformations of the auricle are present in 1% of births today. Correcting a major congenital malformation of the auricle is a true test of a plastic surgeon's skills.

The definition of microtia has been the subject of numerous publications, as clinicians have attempted to define the different grades that exist. This section focuses on the grades of microtia for which surgeons can initiate surgical reconstruction with a high degree of success.

Tanzer (12,13) published the first article on auricular reconstruction using autogenous rib cartilage in 1959. Shortly after, in 1966, Cronin (14) popularized the use of Silastic as an implant material to reconstruct auricles. Brent (15), who first reported his work in 1974, is considered the world's foremost authority on auricular reconstruction to date.

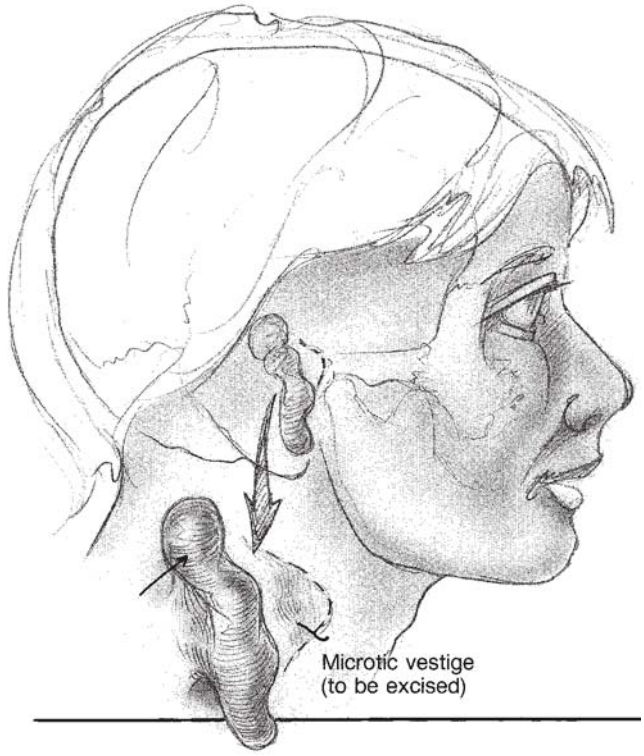

Figure 191.9 Grade III microtia.

Classification

In 1988, Aguilar and Jahrsdoerfer (16) amended the 1926 grading system of Marx, and in 1996, Aguilar (17) reaffirmed this concise classification for congenital ear malformations. Grade I is a normal ear. Grade II has some of the auricular framework present, but there are obvious deformities. Grade III is the standard "peanut ear" deformity, which encompasses anotia (Marx's grade IV) (Fig. 191.9).

The concomitant atresia complicates the classification schemes, yet many try to include it as a criterion: Altmann in 1955 (the first schema based on the temporal bone itself, looking at the status of the canal, tympanic bone, drum, and ossicles) and Lapchenko in 1967 and Gill in 1969 (both set up a four-tier scale, examining the degree of middle-ear and external canal development and the presence of ossicular abnormality). Gill also incorporated into his system the degree of pneumatization of the mastoid because this finding seemed to predict the relative success of operative interventions. Ombredonne, Nager, and Colman each sought to establish simplified and clinically practical systems based on Altmann's original classification, but these systems were inconsistent at predicting outcome in those cases of major aplasia or group II anomalies. Fernandez said that Jahrsdoerfer's 1992 system is a grading scale for selecting patients that would most likely benefit from attempts at repair of their atresia. He commended this scale for its "predictive power." Furthermore, the benefit of the Jahrsdoerfer's system is that it is not subject to interobserver bias and allows for a quantitative analysis of the temporal bone and those structures deemed vital to the success of an operation.

The Jahrsdoerfer scale, based on temporal bone CT findings, assesses nine different parameters that are used in making the determination of candidacy for surgery. Fernandez stated that the stapes and oval window complex account for 3 out of 10 points possible. Other parameters include the middle-ear cleft, facial nerve position, status of the ossicles and round window, and pneumatization of the mastoid. Scores of 6 through 10 range from marginal to excellent candidates for surgery, whereas a score of five or less usually points to a poor outcome.

In 1974, Rogers (18) published a classification system that divided congenital auricular defects into four groups:

1. Macrotia
2. Lop ear
3. Cup ear
4. Prominent ear

In 1977, Tanzer (19) proposed a clinical classification of auricular defects that has been well documented in virtually all articles that have been published since then:

1. Anotia
2. Complete hypoplasia (microtia)
   A. With atresia of the external auditory canal
   B. Without atresia of the external auditory canal

3. Hypoplasia of the middle third of the auricle
4. Hypoplasia of the superior third of the auricle
   A. Constricted (cup and lop) ear
   B. Cryptotia
   C. Hypoplasia of entire superior third
5. Prominent ear

Weerda (20) from Europe in 1988 combined all of the classifications into a concise document. Definitions proposed by Marx and Tanzer and modified by Rogers (21) were presented. This system included surgical guidance for each classification:

1. *First-degree dysplasia*. Average definition: Most structures of a normal auricle are recognizable (minor deformities). Surgical definition: Reconstruction normally does not require the use of additional skin or cartilage.
   A. Macrotia
   B. Protruding ears (synonyms: prominent ears, bat ears)
   C. Cryptotia (synonyms: pocket ear, group IV B [Tanzer])
   D. Absence of upper helix
   E. Small deformities: Absence of the tragus, satyr ear, darwinian tubercle, additional folds (Stahl ear)
   F. Colobomata (synonyms: clefts, transverse coloboma)
   G. Lobule deformities (pixed lobule, macrolobule, absence of lobule, lobule colobomata [bifid lobule])
   H. Cup ear deformities
      i. Type I: Cupped upper portion of the helix, hypertrophic concha, reduced height (synonyms: lidding helix, constricted helix, group IV A [Tanzer], lop ear, minor [mild or moderate] cupping)
      ii. Type II: More severe lopping of the upper pole of the ear; rib cartilage is used as support when a short ear must be expanded or the auricular cartilage is limp.
2. *Second-degree dysplasia*. Average definition: Some structures of a normal auricle are recognizable. Surgical definition: Partial reconstruction requires the use of some additional skin and cartilage (synonym: second-degree microtia [Marx])
   A. Cup ear deformity, type III: The severe cup ear deformity is malformed in all dimensions (synonyms: cockleshell ear, constricted helix, group IV [Tanzer], snail-shell ear)
   B. Mini-ear
3. *Third-degree dysplasia*. Average definition: None of the structures of a normal auricle are recognizable. Surgical definition: Total reconstruction requires the use of skin and large amounts of cartilage (synonyms: complete hypoplasia group II, peanut ear, third-degree microtia [Marx]); normally there is concomitant congenital atresia.
   A. Unilateral: One ear is normal; no middle-ear reconstruction is performed on any child; auricle reconstruction is begun at age 5 or 6 years.
   B. Bilateral: Bone-conduction hearing aid before the first birthday; middle-ear surgery at age 4 years without transposition of the vestige; bilateral reconstruction of the auricle at age 5 or 6 years
   C. Anotia

TABLE 191.4 DIAGNOSIS CONGENITAL MALFORMATION OF THE AURICLE

Age of patient

These recommendations can be questioned, however, and there are alternatives. For bilateral microtia, a bone-conduction hearing aid can be placed at birth. In addition, even in bilateral cases, middle-ear surgery can follow the first two stages of auricular reconstruction rather than being the first procedure (22). Guidelines for diagnosis are listed in Table 191.4.

Surgical Reconstruction of Auricular Deformities

In cases of congenital microtia and concomitant atresia, there should be complete coordination between the otologist and the plastic surgeon. Aguilar, in 1996, (17) presented the concept of the Integrated Auricular Reconstruction Protocol. As shown in Table 191.5, microtia repair is accomplished in five stages. The work of the plastic surgeon should be performed first, and the operation should be staged to facilitate total reconstruction of the microtia–atresia complex.

Despite advances made in technique and imaging in recent decades, disagreement remains on several key issues: the prime time for surgery in general, when to operate on cases of unilateral atresia, and the operability of cases with severe craniofacial malformations. Most agree

TABLE 191.5 TREATMENT CONGENITAL MALFORMATION OF THE AURICLE

Stage	Treatment
I	Auricular reconstruction (creation of a cartilaginous framework with autogenous rib cartilage)
II	Lobule transposition
III	Atresia repair (by otologist)
IV	Tragal construction
V	Auricular elevation

that the earliest age to proceed is 4 to 5 years, thus allowing time for adequate mastoid and middle-ear pneumatization and increasing patient compliance with postoperative care. Also, most clinicians think that surgery should be instigated earlier in cases of unilateral atresia with evidence of cholesteatoma, infection, or very thin atresia plates. Opinions differ in regard to cases of grade II and III unilateral atresia in patients with normal hearing in the other ear. Jahrsdoerfer believes that the benefit of binaural hearing exceeds the risk of facial nerve injury and other complications. De la Cruz also favors early operations on unilateral atresias if CT findings point to a favorable outcome.

Correction of microtia should begin around the age of 6 years, especially for unilateral cases, and the best material is autogenous costal cartilage. By this age, there is sufficient cartilage to permit surgical reconstruction, and the patient is psychologically able to cooperate with the necessary postoperative care. Bilateral microtia and atresia cases can be started at an earlier age, but only if sufficient costal cartilage exists to form a new ear. Historically, use of other sources for the framework has failed. Neither irradiated cartilage nor Silastic has stood the test of time: irradiated cartilage reabsorbs, and Silastic tends to extrude with time. Furthermore, Silastic implants are notorious for their inability to withstand trauma.

In 1997, Williams et al. (23) reported on the use of polyethylene (Medpor) implants in auricular reconstruction. These implants can be used to support skin grafts when used to reconstruct defects in auricular cartilage. Animal model revealed that these implants are well tolerated as replacements for native cartilage in auricular reconstruction. Polyethylene implants tolerated wound exposure as early as 4 days after implantation and showed the ability to heal these wounds by secondary intention and to support skin grafts. Authors surmised that this is because of the extent of fibrovascular ingrowth from surrounding tissue, which allows the implant material to act more like native tissue and less like a foreign body in this setting.

At the University of Antwerp (Wilrijk) in the year 2000, Somers (24), at a Politzer Society Meeting, described major breakthroughs in reconstructive surgery of the auricle, opening new possibilities in the rehabilitation of patients with an absent auricle. Somers reported on clinicians who had adopted 33 bone-anchored prostheses and performed 22 total auricular reconstructions. These clinicians reported that the surgery for an episthesis, as long as the surgeon takes into consideration the conditions of osseointegration, is easy and has no major risks. Postoperatively, patients were satisfied with their prosthesis and wore it all day without discomfort. For the total auricular repair of major congenital malformations, two techniques were used: the Brent technique followed by the Nagata technique. The Brent technique was found to be safe with good results, but the modification by Nagata had two advantages: two operative stages instead of four and a better definition of the reliefs of structure as the antihelix, crus anterior and posterior, and antitragus tragus. As expected, results of total auricular reconstruction improved with experience.

Surgical Planning and Treatment

Preoperative planning should include photographs of the patient. Most important is the proper preparation of the template. In unilateral cases, the template is based on the patient's contralateral ear; in bilateral cases, the model is made from the mother's ear. The site of implantation of the cartilage framework on the side of the head should be properly measured to avoid malpositioning of the ear.

If radiologic examination has not already been done, it should be ordered before surgery. A high-resolution CT scan of the temporal bones should be obtained. Although a CT scan is unnecessary for the microtia, it does provide important anatomical information to the surgical team. As a team, the plastic surgeon and the otologist should explain and discuss the entire course of the planned reconstruction to the patient and family before any surgical procedure.

The auricular reconstruction (Figs. 191.10 to 191.12) is undertaken during stage I. Note that the dissection of the cartilage is extraperichondrial, and there is no stripping of perichondrium at any point during rib harvesting. Stainless-steel 5-0 wire is used to anchor the eighth rib to the sixth and seventh rib complex. This technique is popularized by Brent (25) and produces reliable results when performed by trained surgeons. The most common complication that can occur from stage I procedure is atelectasis; other complications include pleural tear (which should be appreciated intraoperatively in usual circumstances), pneumothorax, pneumomediastinum, chest wall aberration, hypertrophic scarring, and pneumonia.

Stage II involves lobule transposition and is shown in Figures 191.13 and 191.14 (Fig. 191.14 depicts the peanut ear). To avoid protrusion of the lobule, the incision on the back of the ear should be fairly high. The inferiorly based pedicle flap is quite thin; thus, great care should be taken in its handling.

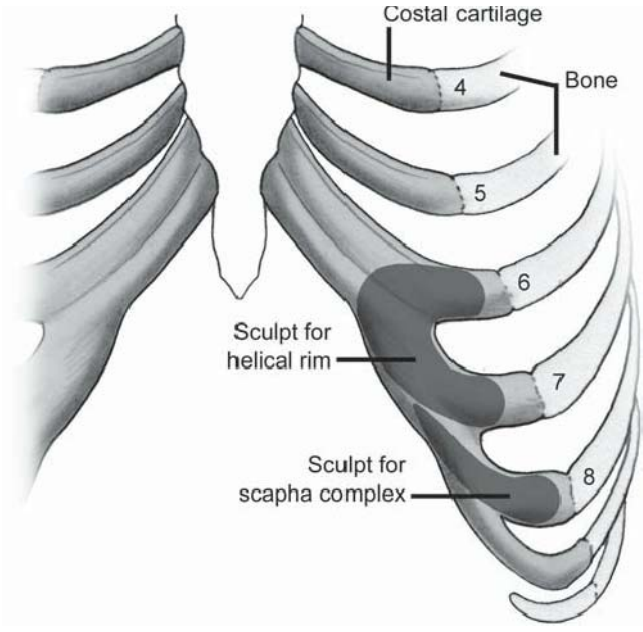

Figure 191.10 Harvesting ribs 6, 7, and 8.

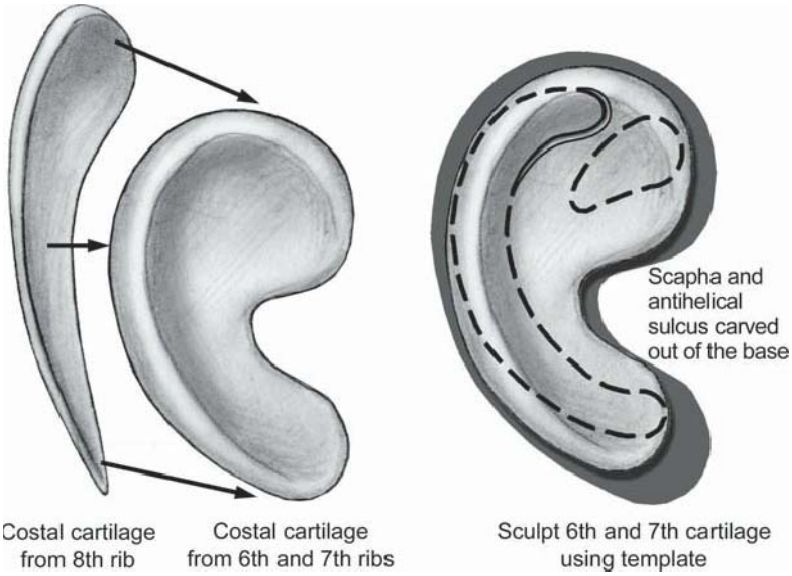

Figure 191.11 Sculpting cartilage to form framework.

Stage III, atresia repair by the otologist, should be undertaken after the first two stages of repair by the plastic surgeon. The temporal bone remnant is in only one location; thus, the opening to that remnant can be made in only one location on the overlying skin. Therefore, it is quite easy to manipulate the framework and line it up where the otologist has drilled the canal. If the otologist drills the canal first, as a stage I procedure, the complication rate is significantly higher, and it is more difficult to place a cartilage framework around an external canal. Moreover, the amount of scarring and the possible compromise to blood flow make complications harder to avoid. The maneuvering of the framework into the proper position on the side of the head is shown in Figures 191.15 and 191.16.

Stage IV, tragal construction, is shown in Figures 191.17 to 191.21. The composite cartilage is taken from the opposite side. Auricular elevation, stage V, is shown in Figures 191.22 and 191.23. The reconstructed ear is shown in Figure 191.24.

Complications

Complications are possible during the surgical reconstruction, as listed in Table 191.6. Placement of the cartilage graft causes severe strain on the overlying skin, which can cause skin necrosis. Skin necrosis of 1 to 2 mm can be treated by the application of ointment and careful observation until skin closure occurs. If the necrosis is greater than 5 mm, the proper course is closure using a pedicled temporal–parietal fascia flap and skin graft. Infection can result in reabsorption of cartilage, and there may be improper placement of the framework. Any grafting procedure always involves the

Figure 191.14 Transposing flap into framework.

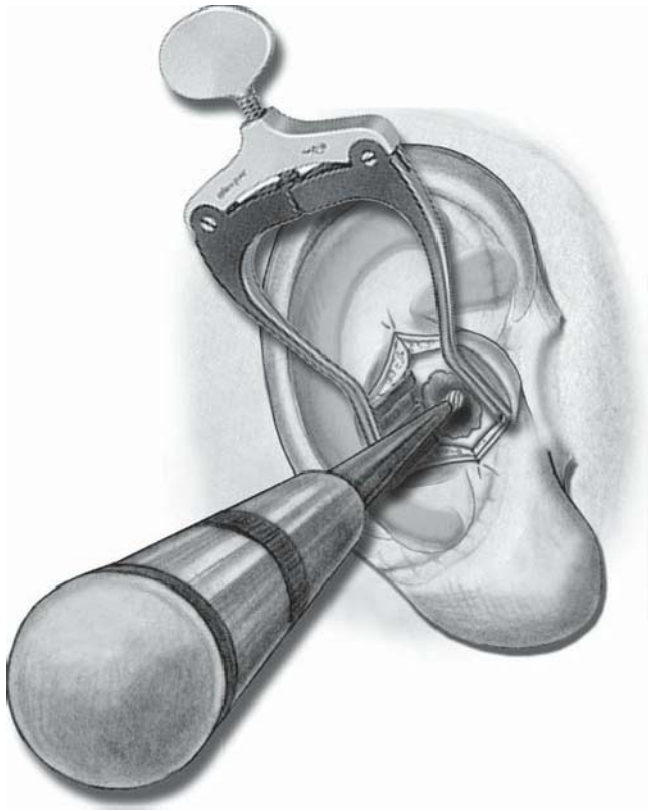

Figure 191.15 Drill-out of temporal bone, creating canal.

risk of graft loss. Finally, the possibility of keloid formation is higher when the graft is harvested from the abdomen or the buttocks. Potential emergencies are listed in Table 191.7.

CONCLUSION

The surgery to correct auricular protrusion is more complicated than it appears. Complications can occur with each of the techniques described, even in the hands of experienced surgeons. The surgery always requires postoperative evaluation, and often the surgeon will not be totally satisfied. Therefore, performing this surgery requires a commitment to continuing education and additional experience. Surgical correction of congenital microtia requires commitment by the facial plastic surgeon, who should be performing more than five to ten operations per year to maintain proficiency. The team approach as described in this chapter is invaluable to the families; failure to offer this approach is a significant disservice to the patient.

The future of auricular reconstruction includes the ever-burgeoning field of tissue engineering. The nexus of cell growth biology and cell scaffolding technology is rapidly changing the landscape of surgical options. Many projects are being undertaken to develop biologic ear cartilage framework (26–29) for implantation. However, the technology still has to overcome issues such as tissue rejection and integrity of form. The use of autologous cartilage or synthetic implants will likely be the mainstay options for reconstruction in the foreseeable future. As with other components of the face, the ear is a very specialized structure and once reconstructed will never have the same properties as a native ear even in the best of hands. With the recent advances in composite tissue allotransplantation (30,31), it is possible that patients may receive an ear transplantation in the future for severe defects.

II	Lobule necrosis
III	None
IV and V	Chondritis

HIGHLIGHTS

- The decision to correct protruding ears is based on the angle of the auricle (greater than 30 degrees) and on other specific anatomic defects of the auricle.
- The helical rim should be 14 to 18 mm above the mastoid skin at the middle and superior thirds.
- The vertical axis of the auricle should be inclined approximately 20 degrees posteriorly.
- A detailed checklist is extremely helpful during the preoperative evaluation.
- The best age to perform the otoplasty surgery is 5 or 6 years.
- Mustardé sutures are horizontal mattress sutures used to create an antihelical fold.
- The Furnas technique must be used with caution. The conchal mastoid suture must be directed posteriorly to avoid narrowing the external auditory canal.
- The most feared complication is chondritis, which should be treated promptly with extensive antibiotic therapy.
- Each patient should be seen on the first day postoperatively to allow early intervention for hematoma or infection.
- Every patient and family should be informed of all risks and made aware that a second procedure may be required later (within a year).

- Every surgeon should learn multiple approaches to otoplasty to be able to offer each patient the best chance for success.
- Autogenous cartilage is best because there is no rejection and limited reabsorption.
- Materials such as Silastic and irradiated cartilage are less than satisfactory alternatives to autogenous cartilage.
- Auricular reconstruction should be performed before atresia repair to preserve the integrity of the skin and the blood supply. Atresia repair should be performed after the plastic surgery, because this allows for the movement of the framework to the proper site.
- Age 6 years is appropriate for unilateral microtia correction, both psychologically and anatomically.
- The framework can be maneuvered to align the meatus and the canal.
- The total reconstruction concept is important. A surgical team should be available to handle both the microtia and the atresia.
- For best results, there should be cooperation with the otologist in the staging of the repair.
- Surgeons performing auricular reconstruction should ensure that the cooperating otologist has completed the necessary audiologic evaluations.
- Each surgeon undertaking auricular reconstruction should be committed to this surgery, performing more than 5 to 10 operations per year.

192 Chin Augmentation

Jonathan M. Sykes *Christina K. Magill*

The chin prominence is not present in any four-legged mammal (1). During evolution, with the adoption of an upright posture and with verticalization of the face, the chin became an important facial feature. The events contributing to the evolutionary development of the chin in humans are open to speculation; however, the importance of the chin in the overall appearance of the face cannot be overstated (2).

Facial beauty arises from symmetry and balanced proportion of all facial features. Although standards of facial beauty are often determined by social media and are time-adjusted, certain elegant features are not affected by time trends. A strong and well-projected chin is one of those features. For this reason, it is not surprising that no United States president has ever had a weak chin. A strong chin helps support the soft tissues of the lower face, and a well-projected chin improves the cervical skin and contributes to a well-defined cervicomental angle (3).

It is important to analyze the chin in three dimensions in order to determine if the deformity is horizontal, vertical, or related to transverse discrepancy or asymmetry (4). Surgical correction of aesthetic deformities of the chin can be performed either by chin augmentation with an implant or by osteotomy and advancement (or reduction) of the bony mentum (5). Simple horizontal deficiencies are often easily corrected with alloplasts. More complex problems of the mentum, such as transverse asymmetry or significant vertical dysmorphia, usually require bony osteotomy of the mentum (genioplasty) with repositioning of the chin into a more ideal three-dimensional position. This chapter outlines the pertinent anatomy and classification of chin deformities and describes an algorithm for correction of these problems.

PATIENT EVALUATION

Careful analysis of the face and chin is important in order to choose and execute the correct procedure. Specifically, the chin should be evaluated as it relates to other skeletal and soft tissue structures, including the lips, teeth, nose, and soft tissues of the neck. A detailed history of past trauma, orthodontic treatment, or prior oral surgery is essential. This is important because many patients with dental malocclusion and underlying facial skeletal abnormalities are treated with orthodontics. Orthodontic therapy may correct the malocclusion, but does not address the underlying facial skeletal deformity (Fig. 192.1). It is also important to identify any past dental extractions, as these can impact future surgical decisions. Lastly, it is important to identify and discuss any temporomandibular joint dysfunction (TMD). Although chin surgery does not directly affect the occlusion, any significant TMD can alter the decision to perform mentoplasty.

Physical examination of the chin should include inspection and palpation of the chin itself and of the adjacent structures such as the lips, teeth, and nose (6). The entire face should be observed at rest and during animation to evaluate the mentalis soft tissue mound and its support. In many patients with either horizontal or vertical microgenia, the mentalis muscle hypertrophies in an effort to create lip competence (7). Overworking of the mentalis muscle causes dimpling of the chin and is referred to as "mentalis strain" (Fig. 192.2). This condition is often associated with open bite deformities and/or microgenia.

Evaluation of patients being considered for chin surgery should include three-dimensional analysis of the chin: (a) vertical (superior–inferior), (b) horizontal (anterior–posterior), and (c) transverse. Analysis should consist of systematic inspection, clinical photographs, and possible radiographic examination (8).

The evaluation of all patients for possible chin surgery should include consistent and reproducible clinical photographs in three views: AP (frontal), lateral (profile), and oblique. These photographs allow analysis of the contour and projection of the chin as it relates to the lips, nose,

Figure 192.1 **Left:** Lateral photograph of a 23-year-old patient who underwent orthodontic therapy as an adolescent. The patient's occlusion was class I, but the skeletal chin deficiency remained. **Right:** Postoperative image of the patient after chin augmentation with alloplast.

labiomental groove, and soft tissues of the neck. If the physical evaluation and clinical photographs show a minor deformity requiring augmentation with an alloplast, radiographs of the chin are usually not necessary. However, if the deformity is more complex (e.g., vertical chin excess with horizontal deficiency or transverse bony asymmetry), radiographic analysis is essential.

Radiographic evaluation of the chin routinely includes a panoramic radiograph (Panorex) (Fig. 192.3) and cephalometric radiographs in the AP and lateral views (Fig. 192.4A and B). The panoramic radiograph shows the cortical outline of the mandible and the vertical mandibular height. The Panorex also delineates the position of the tooth roots and of the inferior alveolar canals and mental foramina. It is important to know the exact position of the mental foramen and canal preoperatively so intraoperative damage to the mental nerve can be prevented (9). The inferior alveolar nerve, a branch of the third division of the fifth (trigeminal) cranial nerve, travels through the mandibular canal and exits the mental foramen as the mental nerve (10). The mental nerve supplies sensation to the skin and mucous membranes of the lower lip and chin. The mandibular canal is often located 2 to 3 mm below the level of the mental foramen. Bony osteotomies should therefore be performed at least 5 mm below the mental foramen to avoid injury to the neurovascular bundle.

If orthognathic surgery is considered with bony genioplasty, AP and lateral cephalometric radiographs should be performed. These radiographs allow analysis of skeletal and soft tissue key points, which can be used to predict bony movements after skeletal surgery. The AP cephalometric radiograph allows identification of transverse asymmetries of the chin. Transverse asymmetry of the chin may be associated with more global facial asymmetry (hemifacial microsomia) or with a syndrome such as oculoauricular vertebral (OAV) spectrum, or may be isolated (Fig. 192.5). It is very important to identify chin asymmetries and discuss them with the patient preoperatively. If chin augmentation is performed with an alloplast implant and the asymmetry is not considered, the asymmetry may be magnified.

Lateral cephalometric radiographs provide a soft tissue and skeletal profile upon which key landmarks can be recognized. The radiograph is with the patient's head being stabilized with a headholder in a fixed position at a fixed distance from the radiograph machine (Fig. 192.6).

Figure 192.2 **Upper left:** A preoperative frontal photograph of a woman with mentalis muscle strain secondary to microgenia. **Lower left:** A lateral preoperative view is shown. **Upper right:** A frontal postoperative view is shown. The patient has undergone a chin augmentation with an alloplast with resolution of the mentalis strain. **Lower right:** A lateral view of the postoperative result is shown.

Figure 192.3 A panoramic radiograph is shown.

The head is stabilized with the Frankfort horizontal (from the porion [the superior aspect of the external auditory canal] to the infraorbitale [the inferior orbital rim]) being parallel to the ground. The standardized radiograph produced allows identification of a series of bony and soft tissue landmarks from which various facial analyses can be performed.

The facial analyses created from the lateral cephalometric radiograph produce a two-dimensional prediction of the new postoperative chin position. Various analyses have been described including Ricketts, Burstone, Gonzalez-Ulloa and Stevens, and others. Each of these evaluation methods has positive and negative aspects. The Ricketts analysis, for instance, uses a tangent connecting the soft tissue pogonion (most projecting point) of the chin with the most projecting point of the nasal tip (Fig. 192.7). In this system, the upper lip should lie about 4 mm behind the line, whereas the lower lip is ideally located 2 mm behind the line. While the Ricketts analysis correctly evaluates the lower face in profile, it places great importance on the projection of the nasal tip. The Steiner analysis uses the columellar inflection point ("S") to identify the correct position for the chin point (8). This method places importance on the lip position. The Holdaway "H" angle relates the position of the soft tissue pogonion with important skeletal points on the mid and lower face. No single analysis is ideal, but each method attempts to determine the "ideal" positions for the soft tissues and skeleton of the chin because these structures relate to the remainder of the face.

The aesthetic unit of the chin and upper and lower lips should occupy one-third of the vertical facial height (Fig. 192.8). The lower facial third height can be obtained by measuring the distance between the soft tissue *subnasale* and the soft tissue *gnathion*. If this distance is greater than one-third of the overall facial height, vertical macrogenia exists. If the distance is less than one-third of the facial height, vertical microgenia can be diagnosed. The lower facial third can be further subdivided into subunits that will indicate specifically from where the increase or decrease in vertical height originates. Two methods exist for subdivision of lower facial heights (Fig. 192.9). The first includes a vertical third from *subnasale* to *upper lip stomion* and two thirds from *upper lip stomion* to the *menton*. The second method divides the lower third into two equal parts, from the *subnasale* to the *vermilion border of the lower lip* and from the *lower lip vermilion border* to the *gnathion*. All of these analyses relate the height of the chin and lower face to the total facial height. In complex chin deformities, a vertical discrepancy as well as a horizontal deficiency or excess may often be present (Fig. 192.10).

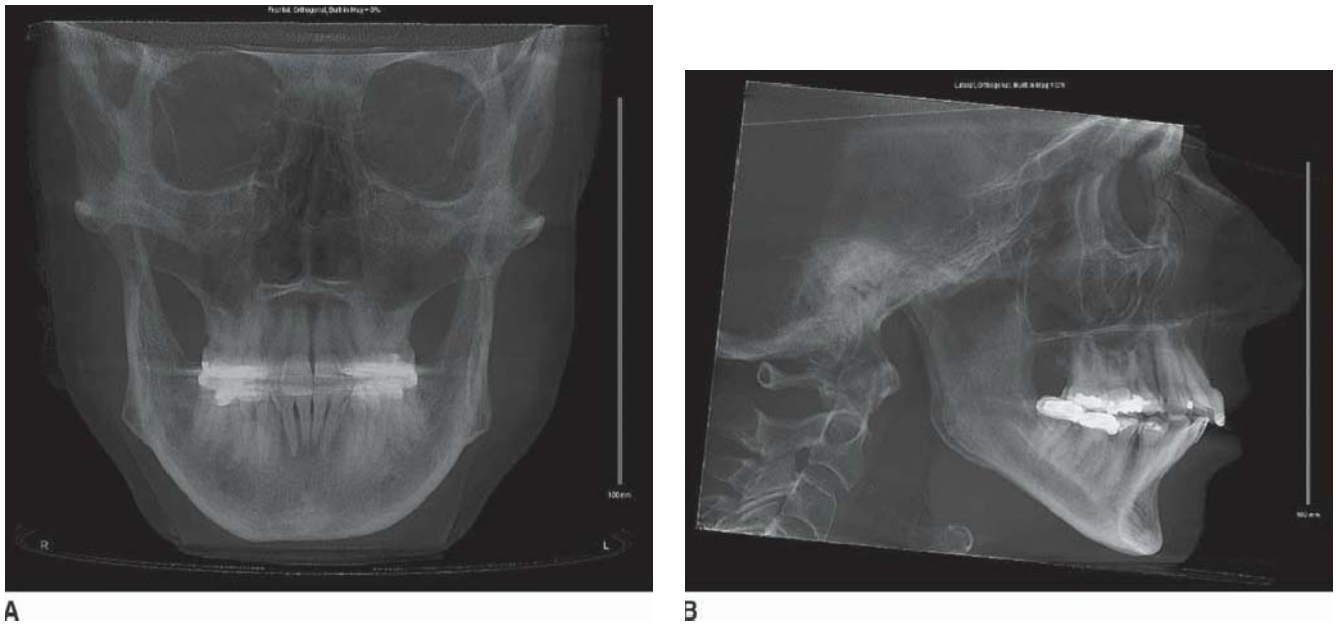

Figure 192.4 **A:** A frontal cephalometric radiograph is shown. **B:** A lateral cephalometric radiograph is shown.

Figure 192.5 Photograph of a 25-year-old female with hemifacial microsomia. A vertical line has been drawn through the center of cupid's bow of the upper lip, demonstrating how the chin deviates to the affected smaller facial side.

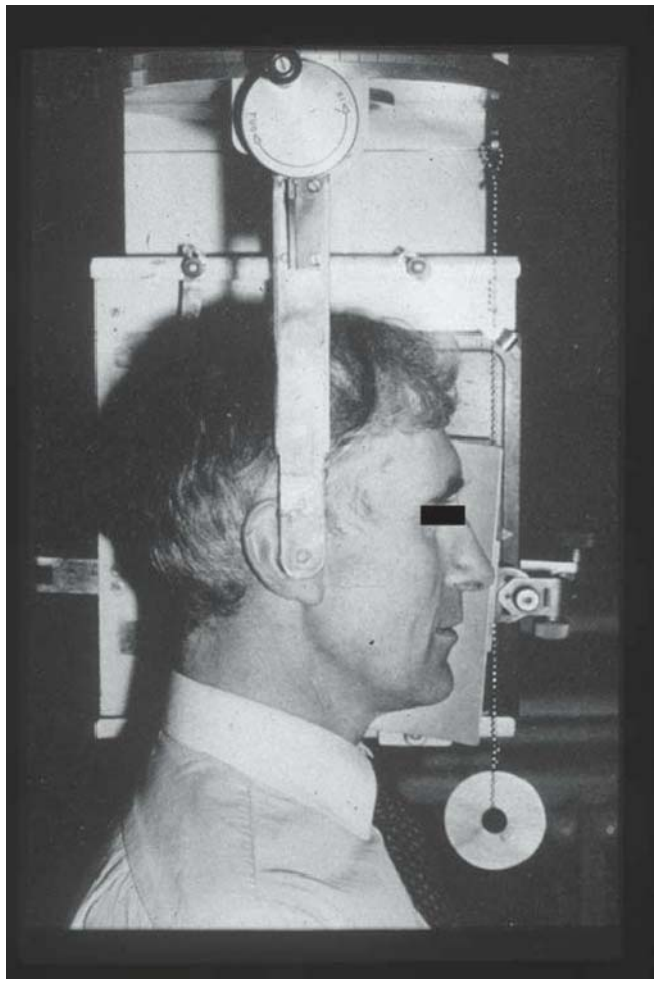

Figure 192.6 A patient in a cephalostat is shown (fixed head holder).

Another parameter that must be analyzed is the transverse dimension of the chin. The transverse dimension can be measured by chin width. The chin can be wide or narrow, and, if asymmetry exists, the midline of the chin may not be aligned with the skeletal midline of the remainder of the face. Transverse asymmetries of the chin exist in many patients with congenital anomalies, such as hemifacial microsomia or OAV spectrum. This congenital malformation is often associated with unequal lengths of the mandibular bodies. In patients with this anomaly, the chin midpoint usually points to the shorter mandibular side (and the smaller side of the face). If a symmetric chin implant is used in a patient with horizontal chin deficiency and transverse asymmetry, the horizontal deficiency may be corrected, but the chin asymmetry may be accentuated. AP cephalometric radiographs allow a comparison of the bony midline of the chin with the dental midlines of the maxilla and the mandible. If the skeletal and soft tissue midline of the chin are not aligned with the dental midlines and with the upper facial skeletal midline (e.g., nasion), an asymmetric bony genioplasty or chin implant can be performed.

Evaluation of the chin requires careful analysis of both the bony architecture and the soft tissues. Clinical photographs allow evaluation of the soft tissues. Radiographs allow various bony analyses, which enable the surgeon to choose the approach and technique to camouflage, minimize, or correct the deformity. No single analysis precisely identifies every deformity, and no one procedure corrects every chin defect. The surgeon should use a combination of methods to evaluate the chin.

Classification of Chin Deformities

Deformities of the chin and lower face may be related to either bony abnormalities or soft tissue malposition. The chin should be analyzed in all three planes of space: horizontal (AP), vertical (superior–inferior), and transverse. The horizontal and vertical dimensions can each be deficient, normal, or excessive (11). Simple deformities such as

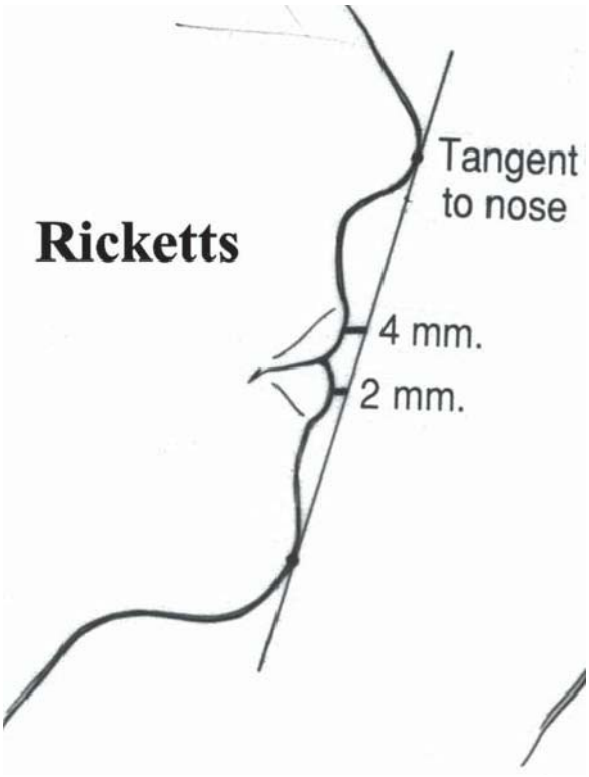

Figure 192.7 Line drawing of the Ricketts analysis showing a tangent between the nasal tip and the most anterior projecting point (pogonion).

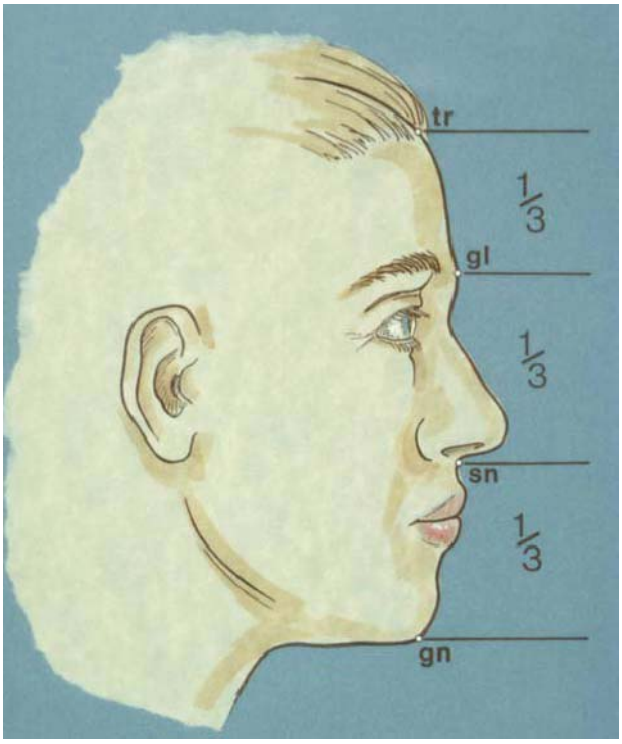

Figure 192.8 A line drawing illustrates the divisions of the face into thirds. The upper third is drawn from the trichion (tr) to the glabella (gl). The middle third is drawn from the glabella to the subnasale (sn). The lower third is drawn from the subnasale to the gnathion (gn).

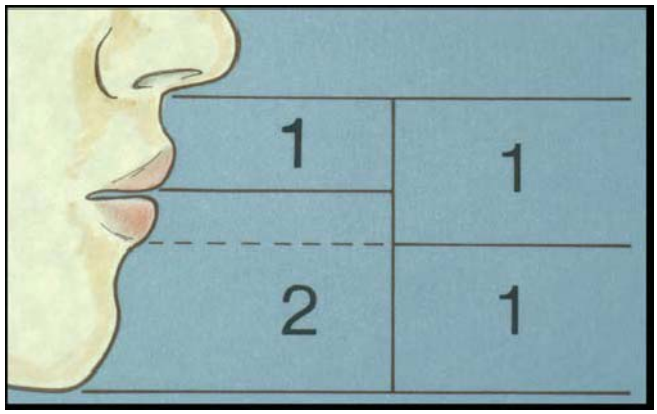

Figure 192.9 Two methods of lower facial analysis are shown: (*1*) The lower face can be divided by a 1/3 ratio from the subnasale to the stomion. The remaining 2/3 of the lower face is drawn from the stomion to the gnathion. (*2*) The lower face is divided into an upper half from the subnasale to the lower lip vermilion cutaneous junction, and a lower half spanning from the vermilion cutaneous junction to the gnathion.

mild horizontal chin deficiency (*microgenia*) are easily corrected using either an implant or bony advancement. More complex deformities, such as in a patient with horizontal deficiency and vertical excess, usually require horizontal osteotomy for adequate correction.

Figure 192.10 A lateral photograph of a patient is shown demonstrating vertical chin height excess and horizontal chin height deficiency.

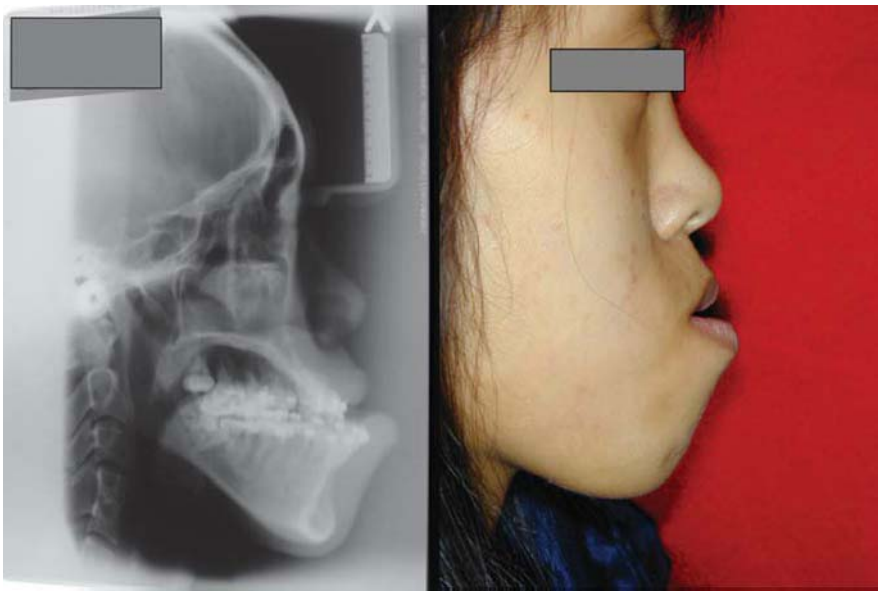

Figure 192.11 Lateral cephalometric radiograph and lateral photograph of a patient with significant vertical macrogenia and mandibular prognathia.

Horizontal chin deficiency is often associated with a small or posteriorly positioned mandible (*retrognathia*) or may involve only a small chin (*microgenia*). Patients with retrognathia often have associated class II malocclusion. Horizontal chin excess is often associated with a large or anteriorly positioned mandible (*prognathia*) or may involve a large mentum only (*macrogenia*) (Fig. 192.11). Patients with mandibular prognathia often have class III malocclusion.

Soft tissue deformities of the chin and submental region also exist. Ptosis of the soft tissues of the chin often accompanies other signs of facial aging. This condition, commonly called witch's chin or senile chin deformity, is caused by a weakening of the muscular attachments of the mentalis and depressor labii inferioris muscles. In this deformity, the soft tissue pad of the chin falls below the mandibular line, and a deep horizontal crease develops in the submental region. Descent of the soft tissue chin pad is accentuated with smiling. This deformity can be inadvertently created or worsened surgically if the mentalis muscles are not reapproximated while inserting a chin implant.

Selection of Procedure

Various procedures exist for correcting aesthetic chin deformities. These include placement of an alloplast, osteotomy and repositioning of the bony mentum (genioplasty), and repositioning of the soft tissues of the chin (12,13). The selection of the best procedure to correct a given deformity of the chin should be based on the type and extent of the deformity.

In patients with horizontal chin deficiency (microgenia), augmentation with an alloplast implant is a simple and effective method to increase chin projection and enhance the profile. In more complex deficiencies, including patients with suboptimal vertical chin height or transverse asymmetries, alloplasts are less effective and often do not entirely correct the three-dimensional deformity. In cases of horizontal deficiency and vertical excess (patients with a steep mandibular plane), a chin implant may correct the horizontal deficiency, but exacerbate the vertical excess. For these reasons, implant augmentation is an effective method of camouflage for minor chin deformities, but may not be satisfactory for complex deformities.

Osteotomy of the bony mentum (osseous genioplasty) is a versatile and reliable procedure for correcting a variety of skeletal chin deformities. First described by Hofer in 1942, this technique involves horizontal osteotomy and downfracture of the chin, with repositioning and fixation of the distal segment. Osseous genioplasty allows advancement or retrusion in the AP direction as well as lengthening or shortening in the vertical direction. Additionally, the genioplasty procedure provides an approach for correction of transverse asymmetries of the chin. Although customized chin implants can be made to correct chin asymmetries, preformed implants are usually symmetrical.

Correction of soft tissue ptosis has been described. The technique involves the removal of an ellipse of submental skin, creation of a flap of chin soft tissue, and advancement and plication of the soft tissue flap inferiorly. This technique tightens the soft tissue pad and obliterates the horizontal submental crease. However, the soft tissue pogonion is effectively moved posteriorly, and some form of simultaneous augmentation (implant or bony advancement) is usually required.

Surgical Procedures

Chin Augmentation with Alloplast Implant

Placement of a chin implant may be easily performed through either an intraoral or a submental approach. If other

central neck procedures, such as submental liposuction, are being performed simultaneously, a submental incision provides access to both the central neck and the mentum. Additionally, either general anesthesia or local anesthesia with intravenous sedation may be used in placement of an alloplast chin implant.

Prior to anesthetizing the chin, the midline soft tissues of the lip, chin, and thyroid cartilage are marked to ensure midline placement of the implant. Infiltration of the soft tissues of the chin with Xylocaine 1% with 1:100,000 epinephrine is then performed to obtain anesthesia and vasoconstriction. It is important to avoid overinflation and distortion of the soft tissues of the chin with local anesthetic. After anesthetic infiltration, the entire face is prepped and draped.

Placement of a chin implant can be performed through an intraoral or submental approach. A submental approach is often used as this approach allows access to the anterior neck for liposuction and/or platysmaplasty. If a neck procedure is being performed, the neck will be completed prior to definitive placement of the chin implant.

A 2-cm incision is made just inferior to the submental crease (Fig. 192.12). The incision is placed in this area to avoid exposing the scar after the stretching of the soft tissues that naturally occurs after implant placement. Sharp dissection is performed through the inferior chin soft tissues and

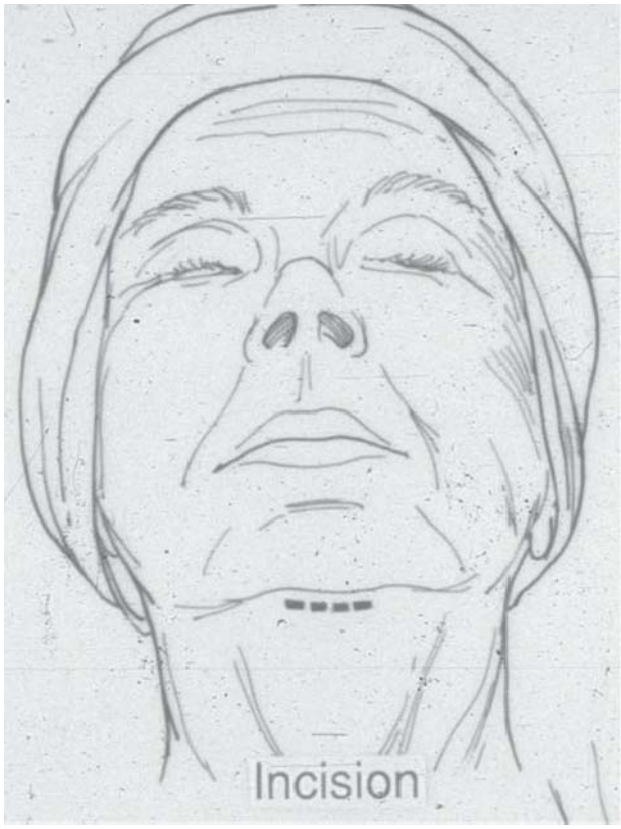

Figure 192.12 Schematic diagram of submental incision.

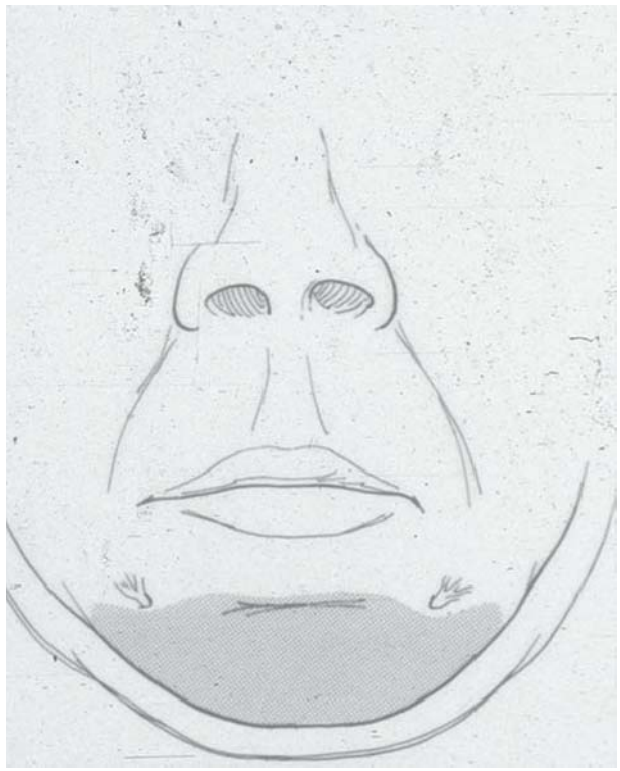

Figure 192.13 The area over the mandible that is shaded illustrates the extent of undermining performed for chin implant placement.

the mentalis muscle (Fig. 192.13). The periosteum is left over the central mentum. Two vertical incisions are made through the periosteum 2 cm lateral to the midline. Bilateral subperiosteal dissections are performed to allow placement of the lateral wings of the implant (Fig. 192.14). The advantage of placing an implant beneath the periosteum is

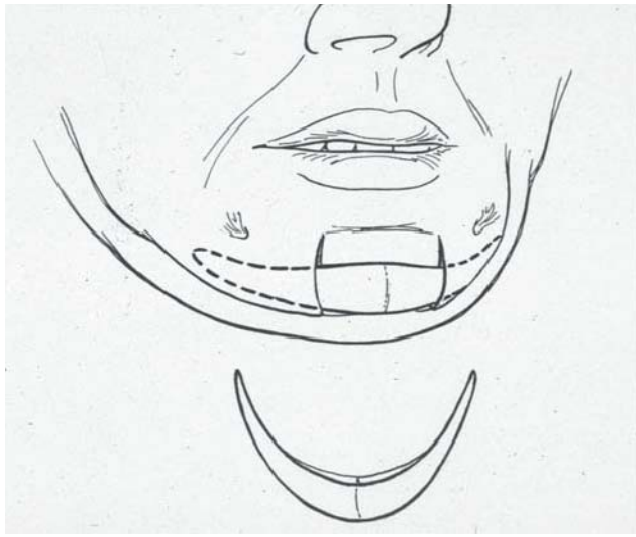

Figure 192.14 Placement of a chin implant is shown with the lateral phalanges lying deep to the periosteum and the middle portion of the implant in the supraperiosteal plane.

improved fixation of the implant. However, subperiosteal placement has been shown to result in some erosion of the anterior mandible. For these reasons, most surgeons advocate dissection in the supraperiosteal plane centrally, with subperiosteal placement laterally. This will theoretically minimize mandibular erosion, while maximally fixing the implant. The subperiosteal dissection is accomplished inferior to the mental foramina to avoid injury to the mental nerves. The size and exact location of the implant pocket created is crucial and often determines the success of the procedure. If the implant pocket is too small, the implant can deform, create irregular contours, or not adhere to the underlying bony mentum. If the pocket is too large, the implant may migrate from the desired midline location and heal in an improper position.

The type, shape, and size of the chin implant used is based on physician preference and individual patient anatomical variation. Common implants used for chin augmentation include expanded polytetrafluoroethylene, silastic (solid silicone), high-density polyethylene (Medpor), and various meshed materials (Mersilene). The implant used should be biocompatible and able to contour well to the underlying mandible curvature. The style of the implants used includes narrow "button" implants and extended or anatomical implants. Extended implants have the advantage of not being as apparent if 1 to 2 mm of displacement occurs. Smaller, central implants are more obvious if slight postoperative displacement of the implant occurs. Additionally, an extended implant is preferred over a narrower, button-style implant, as the wider profile of the extended implant achieves fullness in the pre-jowl region in addition to increasing the projection of the central mentum. A lack of fullness in the pre-jowl region often contributes to an aged or tired look, and augmenting this region helps rejuvenate the lower face.

The size of the implant used is related to the patient's individual chin shape and size. In general, chin augmentation is used to balance the appearance of the lower facial third in relation to the remainder of the face. Prior to placing the actual implant, a "sizer" can be placed into the created pocket and the skin redraped (Fig. 192.15). This maneuver allows the surgeon to determine if the proper size implant has been placed and the appropriate augmentation achieved. Once the proper implant size is chosen, the implant is soaked in antibiotic solution and placed into the prepared pocket.

After placement of the implant, the mentalis muscles should be reapproximated and the soft tissue resuspended meticulously. If the mentalis muscle is not carefully realigned, postoperative ptosis of the soft tissues of the chin may occur. Closure of the mentalis muscle is performed with a No. 4-0 braided absorbable suture. The subcutaneous tissues and dermis are reapproximated with a No. 5-0 chromic suture, followed by skin closure with an interrupted No. 6-0 monofilament nonabsorbable suture (Fig. 192.16A and B). A secure chin strap dressing is placed for 3 days to ensure immobility of the implant. Perioperative antibiotics are used for 48 hours.

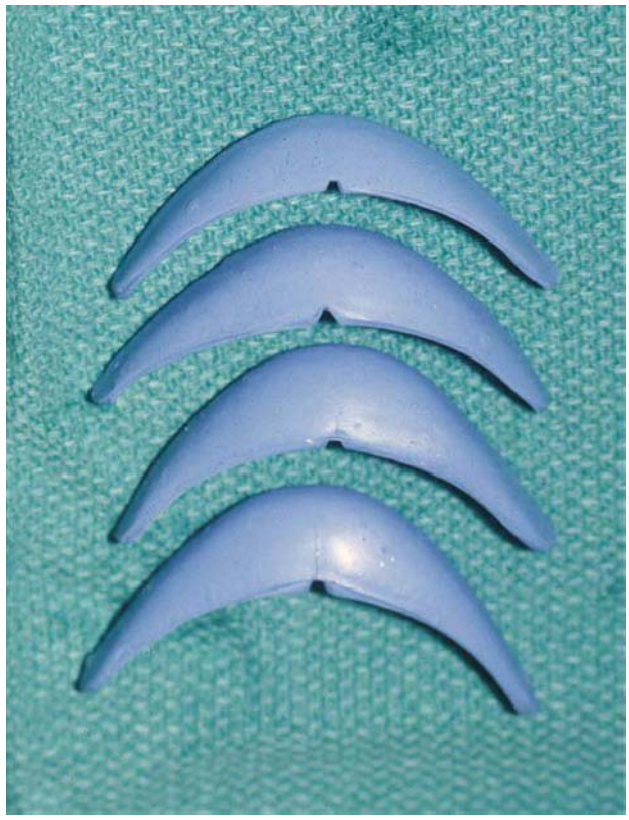

Figure 192.15 Typical size of an extended chin implant with small, medium, large, and extra-large sizes. The photograph shown is of implant sizers (*blue in color*).

If an intraoral approach is used, the gingivolabial incision can be either horizontal or vertical. In either case, dissection through the mentalis muscles again occurs with placement of the implant in a supraperiosteal plane centrally and a subperiosteal pocket laterally. Closure is accomplished in two layers with the muscle closure achieving soft tissue resuspension. A chin strap dressing is used for 3 days to secure the position of the implant.

Osseous Genioplasty

First described in 1942 by Hofer, and then popularized by Converse and Wood-Smith in 1964, osseous genioplasty has been developed as a versatile technique in correction of both deficient and excessive chin deformities. Genioplasty can be performed under general anesthesia or intravenous sedation with mentalis nerve block. If general anesthesia is used, nasotracheal intubation is preferred; however, if rhinoplasty is to be performed with the genioplasty, orotracheal intubation should be used.

An intraoral approach is used with a gingivolabial incision from one canine tooth to the other (Fig. 192.17). The incision is made on the labial side of the gingivolabial

Figure 192.18 A dissection through the mentalis muscle and down to periosteum is shown in preparation for genioplasty.

sulcus to allow an adequate mucoperiosteal soft tissue cuff for wound closure. Sharp dissection is performed directly through the mentalis muscle and mandibular periosteum (Fig. 192.18). A subperiosteal dissection is then performed with exposure of both mental nerves (Fig. 192.19). A small inferior segment of soft tissue is preserved over the central segment (bony mentum) of the mandible to provide vascular supply to the distal segment after osteotomy.

After the lateral subperiosteal dissection is completed, the proposed osteotomy is carefully measured and marked. The bony midline is vertically inscribed with a side-cutting burr to allow the proximal and distal segments to be precisely aligned after osteotomy and repositioning (Fig. 192.20). The osteotomy site is then measured and marked with calipers to ensure a symmetrical osteotomy (Fig. 192.21A and B). The horizontal osteotomy should be placed below the level of the tooth roots to prevent dental injury (Fig. 192.22).

Figure 192.19 Cadaveric dissection of a subperiosteal plane exposing the left mental nerve.

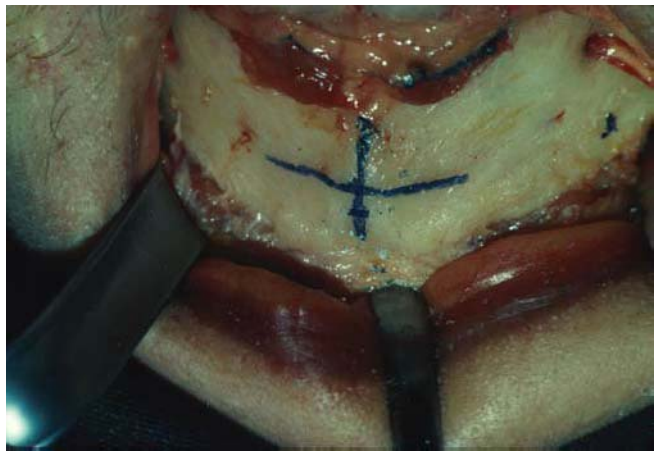

Figure 192.20 Cadaveric dissection showing vertical marking of the midline to facilitate realignment after chin repositioning.

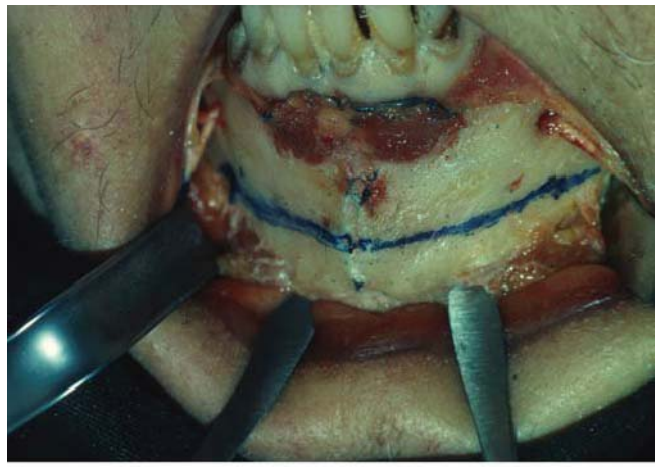
The change created by bony osteotomy and repositioning of the chin should be determined by careful preoperative analysis. The chin can be vertically lengthened or shortened, horizontally advanced or retruded, or rotated



A

B

Figure 192.21 **A:** Cadaveric dissection showing a horizontal marking at the level of the planned osteotomy. **B:** A schematic illustration is shown using calipers that are used to measure the osteotomy site.

Figure 192.22 A cadaveric dissection is shown in which a horizontal osteotomy has been performed approximately 5 mm inferior to the mental foramen.

Figure 192.24 Cadaveric rigid fixation of the mentum in a vertically short chin after placement of bone grafts.

to correct transverse asymmetries. This treatment plan will affect the orientation of the osteotomy as well as the actual movement after the osteotomy. If only AP advancement is needed, the osteotomy is made with a horizontal orientation. If vertical movement (shortening) is needed in addition, the osteotomy is made in a more oblique orientation. An oblique osteotomy allows some vertical shortening because the distal segment is advanced. If the chin length is excessive and significant shortening is planned, two oblique osteotomies are made and the intervening bone is removed.

After the osteotomy is marked, the bone cut is created with either a reciprocating or an oscillating saw blade in a lateral-to-medial direction. The lateral extent of the osteotomy should be made at least 5 mm below the mental foramen to avoid injuring the mental nerve. Gentle digital pressure is used to downfracture the bony segment. A small amount of soft tissue must usually be separated from the posterior aspect of the distal segment to facilitate movement.

Repositioning of the distal segment is performed according to the preoperative treatment plan. If vertical lengthening is required, grafts are placed using autogenous bone or allogenic bone. If vertical shortening is planned, a second parallel osteotomy is made above the first, or the intervening bone is burred away (Fig. 192.23). After the segment is repositioned, it is fixed in position using adaptation plates, positional screws, or interosseous wires (Fig. 192.24). Adaptation plates can be preshaped and provide excellent fixation. The soft tissues of the chin and lips are then replaced, and the new contour is assessed (Fig. 192.25).

The wound is closed in two layers with care taken to resuspend the soft tissues of the chin. Interrupted No. 3-0 catgut is used for the mentalis muscle, and a running locking stitch of No. 3-0 chromic catgut is used for the mucosa.

Figure 192.23 A photograph of a cadaveric dissection demonstrating parallel osteotomies and removal of bone (ostectomy) for vertical chin reduction.

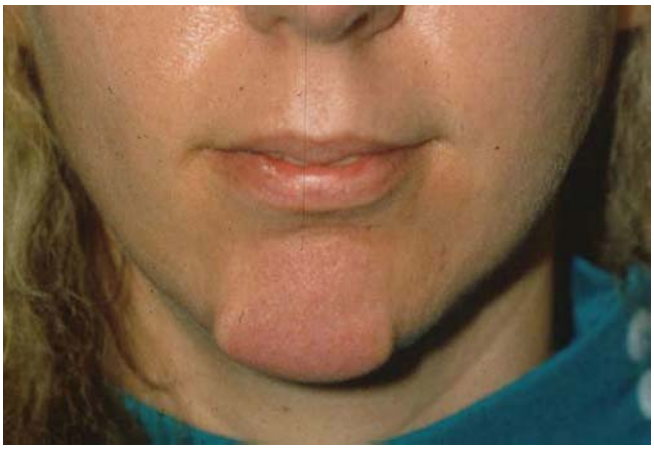

Figure 192.26 Close-up frontal photograph of a patient with a malpositioned chin implant.

A pressure chinstrap dressing is applied for 5 days, and the patient should eat a soft diet for 2 weeks.

Complications

Complications after chin augmentation with an alloplast implant are uncommon. They include hematoma, infection, dysesthesias or anesthesia, and implant malposition. Hematoma and infection are rare and can be avoided with meticulous hemostasis. Sensory nerve disturbances can be minimized with careful anatomic technique. Implant malposition can be avoided by careful creation of an appropriate-sized implant pocket (Fig. 192.26). Chin implants commonly cause mild bony erosion of the anterior mandible (Fig. 192.27). However, this erosion is rarely clinically significant and does not usually cause cosmetic deformity. Finally, mentalis muscle dyskinesis can occur from routine elevation and repositioning of the mentalis muscle. This condition is well treated with 2 to 5 units of botulinum toxin.

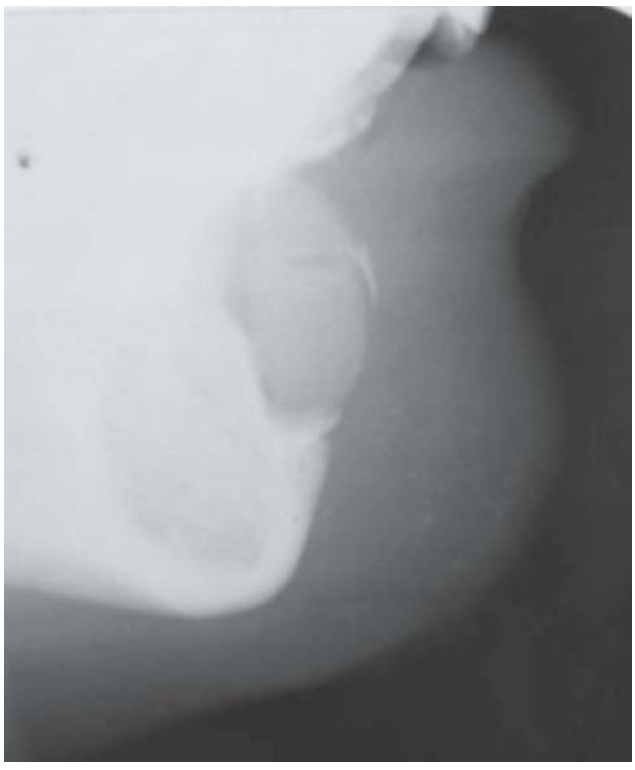

Figure 192.27 Lateral radiograph of a patient with a malpositioned (too superior) chin implant with subsequent bony resorption.

Complications after bony genioplasty also are rare and include hematoma and sensory nerve dysesthesias. Additionally, intraoral wound dehiscence can occur. The incidence of dehiscence is low and can be minimized by a careful, layered closure. Plate exposure and infection can also occur. Mentalis muscle dyskinesis also occurs (with an incidence of 5% to 10% post–chin implant or genioplasty) and can be again treated with injection of 2 to 5 units of botulinum toxin.

SUMMARY

The chin plays an important role in the profile and overall facial appearance. In order to evaluate the chin, analysis of the chin as it relates to other facial features should be performed. Three-dimensional evaluation of the chin includes visual inspection, photographic analysis, and radiographs.

Augmentation of the chin can be performed either with placement of an alloplast implant or with osteotomy and movement of the bony mentum. While placement of an implant is a simple procedure and corrects horizontal chin deficiency, bony genioplasty can correct chin deformities in all 3 dimensions. Additionally, bony genioplasty can also correct both horizontal and vertical macrogenia. If carefully performed, chin augmentation with an implant or genioplasty can dramatically improve the appearance of patients with chin deformities.

HIGHLIGHTS

- The chin plays an important role in the facial profile and in overall facial appearance.
- The chin should be evaluated as it relates to other adjacent structures, such as the lips, nose, and teeth.
- It is crucial to evaluate the chin in 3 dimensions: horizontal (AP), vertical, and transverse.
- Horizontal chin deficiency (microgenia) may be associated with class II malocclusion, while chin excess (macrogenia) may be associated with class III malocclusion.
- Horizontal chin deficiency may be camouflaged by an alloplast implant.
- Bony osteotomy of the mentum (genioplasty) can correct vertical and transverse chin deformities.
- Complications of chin surgery include infection, implant malposition, extrusion, and persistent cosmetic deformity.

193 Redefining Skin Resurfacing: The Hetter Chemical Peel

Devinder S. Mangat

As medical advancements have increased not only our life span but also our quality of life, it is natural to expect a greater public desire to undo the untoward effects of sunlight, age, and genetics. This has created a myriad of unsubstantiated skin care products, and practitioners of wonder technologies promising unrealistic end results. Chemical peeling has withstood both the harshest critics of safety and of results. Starting with lay peelers in the early 20th century, chemexfoliation has provided not only a stalwart treatment for practitioners of skin rejuvenation but also the standard by which other modalities are judged. Various chemical formulations have provided treatment for rhytids, lentigos, dyschromias, and actinic damage. The goal of this chapter is to address some more recent changes in chemical peel techniques; to uproot some old, outdated tenets; and to discuss the versatility of Hetter chemical peels.

BACKGROUND

The history of chemical peeling did not begin in the hands of physicians but rather in those of the lay peelers. In the 1920s, Hollywood was the fertile ground for these early practitioners as the stars of early motion pictures wished to maintain both a youthful appearance and career longevity. It was not until the 1950s and 1960s when physicians wished not only to learn these practices but also to wrestle them away from prominent lay peelers trained by Jean DeDesly and Antoinette LaGasse. Gregory Hetter, in his four-part series in 2000, eloquently describes a detailed history of the passing of the chemical peeling art from the lay peelers to the plastic surgeons of the 1950s and 1960s.

As chemical peeling transformed to the realm of medical science, much literature was produced regarding the experiences of plastic surgeons. Not all experiences were matched with scientific scrutiny. Instead, in some cases, dogma was written and adhered to for decades. Much of this dogma was born out of the use of the Baker-Gordon phenol–croton oil formulation (Table 193.1), the earliest formula widely used by physician peelers.

PATIENT SELECTION

Defining an individual patient's suitability for chemical peeling is paramount for the cosmetic surgeon. Not only does the patient need to be physically suitable for the peel but also the patient needs to have appropriate expectations of what the peel can accomplish. Rhytids and photodamage must be distinguished from age-related gravitational changes, jowling, and facial fat volume loss.

The ideal chemical peel patient is one with fair skin, blue eyes, and mild, shallow rhytids. However, this only represents a minority of the patients who will present seeking treatment for rhytids and photodamage. In order to help define the patient's skin type, the Fitzpatrick scale (Table 193.2) is most often employed. Patients can also be rated by their skin type, complexion, skin texture, thickness, and photoaging. A useful categorizing scheme is the one described by Glogau (Table 193.3).

The patient's medical history and lifestyle must be thoroughly discussed prior to the planning stages of the peel. Relative contraindications for any resurfacing procedure include cutaneous radiation history, smoking, active or frequent herpes simplex virus (HSV) infections, diabetes mellitus, or a history of hypertrophic scar formation or keloids. Birth control pills, exogenous estrogens (including soaps and cosmetics containing lavender oil), or photosensitizing drugs are to be avoided due to risks of hyperpigmentation. Due to elevated estrogen levels of pregnancy, the patient should not have plans to become pregnant within the first 6 months after the chemical peel (1).

Lifestyle and habitual activities, more specifically, sun exposure and smoking, should be addressed. Due to the

TABLE 193.1 THE "CLASSIC" BAKER AND BAKER-GORDON FORMULATIONS

Ingredients	Baker-Gordon Solution	Original Baker Formulation
Phenol USP 88%	3 mL	5 mL
Distilled water	2 mL	4 mL
Croton oil (27 guttas = 1 mL)	3 guttas	3 guttas
Septisol	8 guttas	8 guttas

microvascular damage that ensues from nicotine, a chemical peel in the face of chronic smoking can lead to poor tissue healing and poor cosmetic results. Practitioners should be honest and frank regarding the risks of smoking, and a cessation program should be recommended. Smokers should stop smoking 1 month prior to a chemical peel and should avoid smoking for at least 6 months after the peel. Ultraviolet light (UV) exposure can be equally problematic in the postoperative period. A patient's habitual sun exposure should be assessed prior to proceeding with the peel. The patient should be advised that chronic or frequent sun exposure should be avoided after the chemical peel. If this is unacceptable to the patient, the practitioner should consider other options and not perform a peel.

Isotretinoin (Accutane) use is an absolute contraindication to chemical peeling or any other resurfacing procedure. Postpeel reepithelialization relies upon the epidermis within hair follicles and sebaceous glands. Isotretinoin prevents reepithelialization from these locations. Most recommendations include a cessation period of oral isotretinoin for 12 to 24 months prior to the peel.

The patient's expectations should be clarified and agreed upon with the practitioner. The patient's axillary skin can often well represent the final product of a chemical peel, as long as that area has not had excessive UV light exposure over the patient's lifetime (2).

PREPEEL PREPARATION

Proper skin preparation is essential and contributes to optimizing results and minimizing complications. Preoperatively, the use of sunscreens which block UVA and UVB irradiation will decrease melanocyte activity and prevent skin tanning and sunburns. Sunscreen usage should begin 3 months prior to the peel in combination with minimal sun exposure.

Topical tretinoin (Retin-A) is recommended for 6 to 12 weeks prior to the peel. Animal studies have demonstrated clinical and histologic healing benefits of tretinoin prior to dermabrasion. Synergistic qualities of pretreatment topical tretinoin and trichloroacetic acid (TCA) peels have been shown to sustain the effects of the chemical peel (3,4). Tretinoin aids in reepithelialization (5) and leads to increased melanin distribution. After tretinoin treatment, the thickened epidermis displays decreased corneocyte adhesion, decreased stratum corneum thickness, and neocollagen production, all of which are beneficial to the peel and the postoperative result. This thickened and uniform epidermis aids in the uniform application of the peeling agent (6).

The patient should begin nightly treatments with topical tretinoin 6 weeks prior to the peel, and these should be continued after the postpeel reepithelialization is

TABLE 193.2 FITZPATRICK CLASSIFICATION SCALE

Skin Type	Skin Color	Characteristics
I	White; very fair; red or blond hair; blue eyes; freckles	Always burns, never tans
II	White; fair; red or blond hair; blue; hazel or green eyes	Usually burns, tans with difficulty
III	Cream white; fair with any eye or hair color; very common	Sometimes mild burn, gradually tans
IV	Brown; typical Mediterranean Caucasian skin	Rarely burns, tans with ease
V	Dark brown; mid-eastern skin types	Very rarely burns, tans very easily
VI	Black	Never burns, tans very easily

TABLE 193.3 GLOGAU CLASSIFICATION SCALE

Skin Class	Description
I	"Early Wrinkles" Patient age: 20s–30s Early photoaging Mild pigment changes Minimal wrinkles No "age spots"
II	"Wrinkles in Motion" Patient age: 30s–40s Early to moderate photoaging Appearance of smile lines Early brown "age spots" Skin pores more prominent Early changes in skin texture
III	"Wrinkles at Rest" Patient age: 50s and older Advanced photoaging Prominent brown pigmentation Visible brown "age spots" Prominent, small blood vessels Wrinkles, even at rest
IV	"Only Wrinkles" Patient age: 60s or 70s Severe photoaging Yellow-gray skin color Prior skin cancers Precancerous skin changes (actinic keratosis)

completed. The dose range recommended is between 0.025% and 0.1%. However, there is no literature describing an improved benefit with the higher dosing, suggesting that lower concentrations may be just as effective. Concentration of tretinoin becomes important in those patients who are sensitive to its use. The patient should be warned of the potential side effects including irritation, erythema, and flaking of the skin. When these complications are observed, the dose should be decreased or its use should be discontinued altogether.

Also beneficial in the pretreatment of all peel patients, hydroquinone is most effective in those patients with lentigos, dyschromias, and Fitzpatrick type III, IV, V, and VI skin types, due to the higher risk of postpeel postinflammatory hyperpigmentation (PIH). Hydroquinone blocks the conversion of tyrosine to L-dopa by tyrosinase, thus decreasing melanin production. Hydroquinone, in a concentration of 4% to 8%, should be started 4 to 6 weeks prior to resurfacing. Like tretinoin, hydroquinone should be started after the peel as soon as the patient's skin can tolerate its application.

Even if patients have no recollection of prior herpetic vesicle occurrence, all patients should be warned of the possibility of HSV outbreaks. Patients can have a latent infection even in the setting of a negative history. Common and advisable practice is to start any patient with a negative history on a prophylactic dose of antiviral medication, such as acyclovir 400 mg three times a day, 3 days prior to and continued for at least 7 days after the peel. For those patients with a positive history of active HSV infections, a therapeutic dose of antiviral medication should be employed, such as valacyclovir 1 g three times a day for the aforementioned time period. Postpeel herpetic infections can be unnerving for the practitioner but are devastating for the patient. Therefore, all precautions should be taken to avoid them.

In order to maintain appropriate and uniform depth of penetration of the peeling agent, avoidance of waxing, dermabrasion, and electrolysis should be strictly maintained for 3 to 4 weeks prior to peeling.

BASIC SCIENCE OF HETTER CHEMICAL PEELS

For years, a number of dogmatic suppositions had been purported within the literature regarding the phenol–croton oil peel. These statements date back to the late 1950s and early 1960s when the phenol–croton oil formulas were introduced to the plastic surgery arena. It was from lay peelers from Hollywood in the 1920s and the Miami area in the 1950s that plastic surgeons were able to tease away secret, long-used phenol-based peeling solutions (7). Most formulas contained similar concentrations of croton oil. Litton was the first to present one of these formulas to the American Society of Plastic and Reconstructive Surgery in the late 1950s. However, it is Baker who was credited for the formula he presented in November 1961 and then modified to his classic formula in 1962 (8).

Around the same time that Baker's classic formula was described, Adolph Brown presented three dogmas of phenol peeling. First, that increased concentrations of phenol (80% to 90%) prevented deeper peels by causing an immediate keratocoagulation that prevented further penetration of the phenol solution. Second, Brown believed that by adding a saponin the depth of penetration of phenol increased. Third, he believed that croton oil's role was simply to "buffer" the solution (9). The literature regarding chemexfoliation in the 1960s quickly adopted these assertions and upon them created more dogma. These statements included that phenol was the one and only active ingredient within the Baker formulation and that phenol in lower concentrations penetrated more deeply than in higher concentrations. As a result of these assertions, it was felt that lower concentrations of phenol were more dangerous due to their deeper penetration. As well, it was supposed that septisol caused a deeper penetration and that croton oil had no physiologic role in the peel. Since Brown's assertions in the early 1960s, there have been no scientific studies, animal or human, that lend support to his postulates. That is, until Gregory Hetter, in the late

1990s, questioned these assertions and, more importantly, questioned croton oil's role, or supposed lack thereof, in the standard Baker formula.

Croton oil is pressed from the seeds of *Croton tiglium*, a small shrub found in India and Ceylon. The oil consists mainly of oleic, linoleic, myristic, and arachidonic acids (10). Less than 5% of the oil is made up of a resin, which has been known since 1895 in scientific literature to possess irritant and toxic properties. In 1935, Joseph R. Spies isolated this toxic resin and applied it to the arm of a volunteer, creating severe vesiculations of the skin and a resultant wound taking almost 3 weeks to heal (10). Spies also showed that croton oil was soluble in ethanol and benzene and that it was poorly soluble in a 50:50 phenol to water solution (10). Hetter theorizes that these findings were the basis for using a surfactant, septisol, in the Baker formula.

To refute Brown's postulates and to help elucidate the role of croton oil, Hetter found a patient who was willing to undergo multiple chemical peels of different concentrations of phenol and croton oil. His findings contradicted that which had been previously assumed. At the lowest concentration of 18% phenol, there was minimal post-peel effect. Mild keratolysis occurred with 35% phenol, but there was no clear dermal effect. Hetter noted some desquamation with mild dermal effect after the 50% phenol peel. It was only with 88% phenol that Hetter noted an obvious upper dermal effect, which took 4 to 5 days to heal. With the addition of croton oil, a more profound dermal effect ensued. And, with different croton oil concentrations, there were different healing times. A 0.7% croton oil concentration application required a 7-day healing time, while a 2.1% croton oil concentration, equivalent to that of the classic Baker formula, resulted in an 11-day healing period (10).

From his experience with this one patient, Hetter deduced that phenol peels penetrate more deeply with increased concentrations, that higher concentrations of phenol (88%) without septisol peels penetrate more deeply than lower concentrations (50% and 35%), and that the resultant peel is deeper with increasing concentrations of croton oil.

Hetter used his experience to guide his treatment of five additional patients with varying croton oil concentrations. The results from these five patients allowed him to devise some generalizations of phenol–croton oil peeling. First, the dilution of croton oil, in a constant phenol concentration, shortens the healing time, suggesting a more shallow depth of penetration. Next, he generalized that phenol concentration has little to do with depth of injury. He confirms the observation of Stegman (11) in 1980, which was reiterated by Stone and Lefer (12) in 2001, that multiple coats of peel solution will increase the depth of injury. Obagi (13) first described the need for different depths of peeling for individual subunits of the face. Hetter translated this to his use of varying concentrations of croton oil in different regions of the face. While he found that the lower nose could tolerate croton oil concentrations up to 1.2%, the cheeks and forehead only tolerated concentrations up to 0.8%, and the upper nose, temple, and lateral brow could only withstand concentrations up to 0.4% before the risk of complications rose. Last, Hetter felt 1% croton oil solutions were the upper threshold for safe use to avoid serious risk of hypopigmentation.

Initially, Hetter performed his preliminary work using phenol as a "vehicle" at 33% for the croton oil with one-drop (0.35%), two-drop (0.7%), and three-drop (1.1%) formulations. However, he felt it would be optimal to have a more standardized means of measuring the croton oil concentrations, instead of relying on droppers, which are inherently inconsistent. He converted drops to cubic centimeters by having 25 drops equal 1 mL. Using this conversion, he created a stock solution of 0.04 mL of croton oil per 1 mL of phenol, from which he could make varying croton oil concentrations of 0.4%, 0.8%, 1.2%, and 1.6% in a constant phenol concentration, needing only septisol, phenol, and water. Using his formulations, the practitioner can decide between a phenol concentration of 35% or 48.5%. Table 193.4 depicts the formulas for the varying croton oil concentrations for the Hetter peels using a phenol concentration of 35%.

While Hetter demonstrated that the depth of penetration is partially dictated not only by the components of the peeling solution but also by the concentrations of the components,

TABLE 193.4 THE HETTER PEEL FORMULA

Croton Oil %	0.2%	0.4%	0.8%	1.2%	1.6%
Water	5.5 mL	5.5 mL	5.5 mL	5.5 mL	5.5 mL
Septisol	0.5 mL	0.5 mL	0.5 mL	0.5 mL	0.5 mL
Phenol 88%	3.5 mL	3.0 mL	2.0 mL	1.9 mL	0.0 mL
Stock Solution	0.5 mL	1.0 mL	2.0 mL	3.0 mL	4.0 mL

Adapted from Hetter GP. An examination of the phenol-croton oil peel: part IV. Face peel results with different concentrations of the phenol and croton oil. *Plast Reconstr Surg* 2000;105(3):1061–1083.

Stone emphasized the importance of how application of these varying concentrations must be controlled to create desired results. Stone tested Hetter's posits by performing peels on three case studies using Hetter's varying concentrations, the classic Baker formula with and without croton oil, and varying phenol concentrations without croton oil.

In his first patient, he was able to show on repeat biopsies that the classic Baker formula with and without croton oil would create the same depth of penetration and injury with repeated rubbings and occlusive taping. In the second case, he peeled the patient with alternating concentrations of phenol, 50% and 88%, and alternating concentrations of croton oil, 2.2% and 0.4%, on both thick forehead skin and the thinner nasojugal trough skin. As well, he varied the number of rubs with a wrung-out gauze on the nasojugal trough. On biopsy, he found that all formulas created equal histologic results and similar fibrosis, when applied with 50 rubs. But, by decreasing the number of rubs, he confirmed Hetter's findings that by increasing phenol concentration, the depth of penetration increases. These findings suggest a threshold of injury can be achieved with phenol and croton oil; that threshold can also be achieved by varying concentrations when enough applications are employed. This was confirmed with his third case, in which he used lower phenol concentrations with 2.2%, 0.4%, and 0% croton oil. He found that this aforementioned threshold could be met with all three solutions, but with varying numbers of applications. Stone and Lefer (12) conclude that croton oil serves to lower the threshold number of applications.

Stone's work emphasizes the important point of how the peeling solution is applied to the skin is as important as what active agents are present within the solution. The author feels this is where the experience of the peeler and the "art" of peeling becomes important.

TECHNIQUE

Application of the peeling solution should always be done on sufficiently prepared skin. This preparation begins with vigorous cleaning, with septisol or an acne wash, the evening before and the morning of the procedure.

Preoperative oral sedation, 10 to 15 mg of diazepam and 100 mg of Dramamine, helps relieve the patient's anxiety regarding the intravenous (IV) catheter placement and the upcoming procedure. The antihistamine also reduces oral secretions and helps to protect the patient's airway during periods of deeper sedation. IV fluids should be initiated prior to bringing the patient to the operating room. At this point, additional IV benzodiazepine can be administered if the patient continues to be anxious.

While in a seated position, the patient's submandibular shadow is marked. This step is important to avoid obvious postoperative delineation between peeled and nonpeeled areas at the jawline. The patient is then placed in the supine position. After administering a sedating dose of propofol, the nerve blocks (supraorbital, infraorbital, mental) and field blocks are performed with an equal mixture of 2% lidocaine and 0.5% bupivacaine. The use of epinephrine is avoided, even in the nerve blocks, to allow maximal clearance of phenol. While waiting for maximal anesthesia to occur, the face is thoroughly degreased with an acetone-soaked gauze. Any residual oil on the skin will cause an uneven peel. The acetone cleaning can be repeated throughout the procedure if necessary.

Both Obagi and Hetter recommend using wrung-out cotton, 2-inch by 2-inch gauze, for the application of the peeling agent (10,14). However, the author feels wide cotton-tipped applicators are superior for control of application. As previously mentioned, the depth of the peel is dependent upon the amount of solution on the cotton tip, the uniform application of the solution, as well as the number of strokes applied.

One of the benefits of using a phenol-based solution is that the resultant frost is almost immediate, compared to TCA where the practitioner must safely wait 3 to 4 minutes before assessing a peeled area for needed repeat applications (15). The assessment of peel depth is based on the level of frost observed. In contrast to the TCA peel where the level of frost cannot be determined for 3 or 4 minutes, the phenol-croton oil peel depth can be determined within 20 or 30 seconds. Therefore, areas in need of deeper peeling may be treated again more rapidly. Medium-depth peels create a level II to level III frosting (15) (Table 193.5).

The subunits of the face should be divided by degree of rhytids, lentigos, and photodamage as well as inherent thickness. The author's experience has been to use 0.8% croton oil Hetter solution in areas of deeper rhytids (Glogau III and IV) and thicker skin, such as the perioral, glabellar, and lateral periorbital areas. The intermediate areas (Glogau II and III), such as the inferior periorbital area, are treated with 0.4% croton oil Hetter solution. In order to even the appearance of the face, a simple 88% United States Pharmaceutical (USP) phenol solution is used for all other areas.

An appropriate period, 10 to 15 minutes, must be allowed between each subunit peeled to allow for proper clearance of the phenol solution. The entire face should be peeled over 90 to 120 minutes. In the event that a minor supraventricular arrhythmia occurs, the peel should be stopped, and the practitioner should wait for a return to normal sinus rhythm. The peel should be carried into

TABLE 193.5 CLASSIFICATION OF THE DEGREE OF FROSTING OBTAINED WITH CHEMICAL PEELS

Level I: erythema with stringy or blotchy frosting
Level II: white coat with erythema showing through (should be used for eyelids and areas of bony prominences, i.e., zygomatic arch, malar, chin; higher rate of scarring)
Level III: solid white frost with little or no background erythema

the hairline, as phenol and croton oil will not affect pigment of the hair follicles. The edge of each peeled area will have a margin of reactive hyperemia, which does not represent peeled skin but rather an unpeeled skin reaction. When peeling the adjacent areas, this line of hyperemia (Fig. 193.1) should be included and adequately peeled to avoid obvious lines of demarcation. Similarly, the peel should be carried over the vermilion border. The practitioner can stretch wrinkled skin to allow an even peel over these areas. For deep perioral rhytids, the cotton-tipped applicator can be broken and the wood edge used to apply the peeling agent in the rhytid.

There is no need for neutralization of the peeling solution as the frost represents a completed reaction, which is precipitation of the keratin by the phenol. Great care must be taken around the lower eyelid margin. The peel should be performed to within 3 mm of the ciliary line and stopped. There should be no excess solution on the lower lid. The patient may develop tearing during the procedure. Any tearing should be immediately dried to avoid the tears pooling the peeling solution into the eye. If not adequately anesthetized, the patient will experience an immediate burning sensation for 15 to 20 seconds. However, this sensation will return in 20 minutes and can last 4 to 8 hours later. The longer-lasting effect of the bupivacaine will greatly aid in minimizing the burning sensation in the postoperative period. Therefore, it is essential to perform adequate nerve and field blocks. Even with all precautions in place, accidents may happen. In the case of excess phenol exposure to the patient or the staff, propylene glycol, glycerol, olive oil, castor oil, or cottonseed oil should be poured onto the site to solubilize the phenol. If exposure to the eyes occurs, mineral oil should be immediately applied to the eyes using an eye dropper.

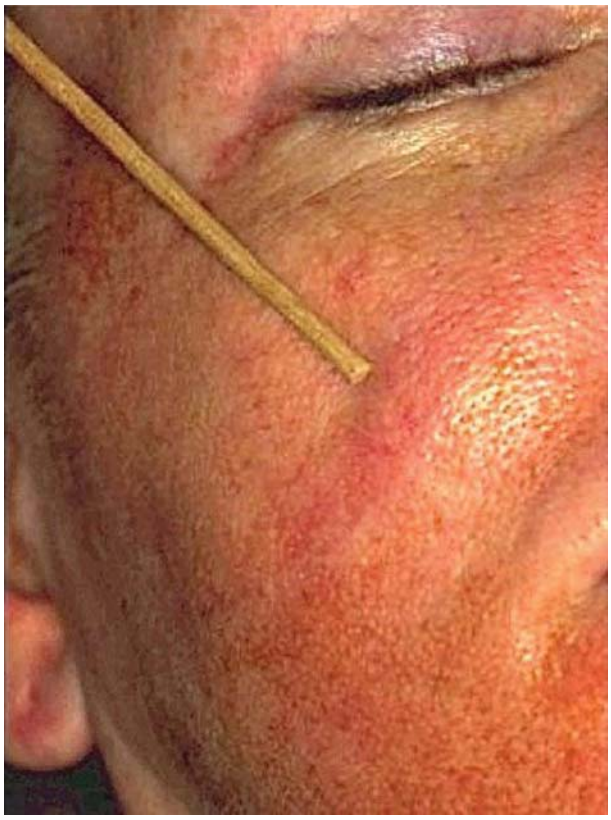

Figure 193.1 This demonstrates the clear line of hyperemia that occurs at the periphery of a peeled area. This hyperemic skin has not been peeled. Care must be taken to peel this area so as to not leave a discrete line of unpeeled skin.

POSTOPERATIVE CARE

Postoperative care begins immediately after the last subunit is peeled.

When the frost subsides and only erythema persists, a thick layer of bland emollient should be applied to all peeled areas, leaving no peeled skin exposed. The senior author prefers Eucerin cream, but Elta or antibiotic ointment may be used. None of these topical agents act as an occlusive dressing, and they will therefore not increase the depth of penetration. Starting with postoperative day 1, the patient will apply the cream three to four times a day to those areas that are exposed. By using the emollient, the peeled skin can be monitored with greater ease on a day-to-day basis.

The patient should have been preoperatively prepared for the expected postoperative edema, erythema, and eventual desquamation. Additionally, patients should also be advised of the burning sensation that may last up to 8 hours following the procedure. The patient's preoprative awareness will aid in the patient's analgesia. The patient should be prescribed an oral narcotic for the postoperative period. The healing process occurs in four stages (15). First, inflammation occurs and increases during the first 12 hours. Next, the epidermis will begin to change in appearance, becoming leathery, and will separate from the dermis. The underlying dermal injury will become necrotic and slough. The emollient will aid in clearing this necrotic tissue from the underlying dermis, which is then recovered with the emollient. Desquamation will occur over 4 to 7 days, exposing the underlying erythematous dermis. The reepithelialization, which typically begins in 48 to 72 hours, will continue through day 7 to 10 (Fig. 193.2), depending on the depth of the peel (15). This reepithelialization will be represented by a conversion of bright red erythema to a lighter shade of pink. The benefit of the peel is born out of the fourth and final stage. This final stage of fibroplasia begins within the first week and continues for 12 to 16 weeks after the peel. This period is marked by neoangiogenesis, new collagen formation, and reorganizing of the collagen.

In the first 12 weeks after the peel, the patient is susceptible to UV light exposure and a resultant hyperpigmentation. Strict avoidance of direct, prolonged sun exposure should be encouraged for that 12-week period. It has been the author's experience that sunscreens should also be avoided for the first 6 weeks. Paraaminobenzoic acid,

Figure 193.2 Erythematous neoepitheliazation has replaced the sloughed chemoexfoliated skin in this patient who underwent a Hetter chemical peel approximately 7 days ago.

found in many sunscreen preparations, can cause an undesirable reaction, including irritation, increased erythema, and induration. Figures 193.3 to 193.7 demonstrate the exceptional results that are obtained from Hetter peels in the treatment of dyschromia and rhytids.

Women of childbearing age should avoid birth control pills or pregnancy. Increased circulating estrogens can result in hyperpigmentation following chemexfoliation.

COMPLICATIONS

Despite taking all necessary preoperative precautions and measures, the busy practitioner can encounter a litany of postoperative complications. A comprehensive understanding of these complications and their management will serve the peeler well. Proper management of these complications, both minor and major, will make the difference between undesirable and optimal results.

Probably the most feared complication of phenol peels is cardiac arrhythmias. Though no death due to phenol peeling has been described in the literature, the possibility of a potential cardiovascular crisis has led to great fear regarding the use of phenol. Even in patients preoperatively screened and well hydrated, a reversible arrhythmia can occur, especially in patients with undiagnosed myocardial sensitivity. These patients will develop a supraventricular tachycardia within 30 minutes of the onset of the peel, which if exacerbated, can progress into paroxysmal ventricular contractions, paroxysmal atrial tachycardia, ventricular tachycardia, and, possibly, atrial fibrillation. The key is to not allow this progression to occur. Once an irregular rhythm is noted, the peeling should be halted, adequate hydration continued, and the patient's rhythm will return to baseline as the phenol is cleared. At this point, the chemical peeling can proceed, but with vigilant observation of

the cardiac rhythm. In the rare cases in which the cardiac rhythm does not return to normal, proper measures should be employed to treat the aberrant rhythm.

Although not as concerning as arrhythmias, prolonged healing times is a nuisance both for the patient and the practitioner. Any area that does not reepithelialize by day 10 should be considered prolonged. Lack of reepithelialization is more common with medium-depth TCA and deeper phenol peels (16). If the wound healing is delayed, daily wound checks should be performed. The practitioner must rule out the presence of infection and treat accordingly. These areas should be treated promptly or they will result in increased risk of scarring.

In the event that scarring occurs, it is going to occur most often in the perioral area, specifically the upper lip. Scarring is most often the result of too deep a peel or from poor postoperative care. The risk of scarring is increased in isotretinoin users. Again, after discontinuing isotretinoin, the practitioner should wait until the patient is clearly developing skin oil. These scars can be treated with Silastic (cross-linked polydimethylsiloxane polymer) sheeting and intralesional steroid injections (Kenalog 20 mg/mL) every 2 to 3 weeks. Overuse of steroids can result in dermal atrophy; therefore, judicious use is recommended. If these scars are erythematous, multiple treatments with a flashlamp-pumped dye laser are helpful (2).

A bacterial pyoderma can aggravate wound healing and lead to scarring. In the rare case of a bacterial or fungal infection, appropriate antimicrobials should be initiated and continued for a 7- to 10-day course.

Similarly, a herpetic infection can be devastatingly uncomfortable for the patient. If, despite prophylaxis, this infection occurs, a maximal antiviral course, valacyclovir 1 g three times a day for 10 days, should be used.

The postoperative erythema that is typical in all peeled patients may last longer than expected. This is more prevalent with patients with sensitive skin or in cases of contact dermatitis. Topical hydrocortisone (2.5%) lotions are helpful for accelerating the resolution of this erythema.

As the erythema is subsiding, some patients, as a result of inadvertent sun exposure or from darker skin type, will develop PIH. This usually occurs weeks after the peel. This is most readily seen in skin overlying bony prominences, such as the lateral malar regions. This is more common in the Fitzpatrick III to VI skin types. A combination of 0.05% retinoic acid, 8% hydroquinone, and hydrocortisone cream is effective at reducing or eliminating this pigmentation. Glycolic acid lotion has been noted to be affective as well (2).

More problematic than hyperpigmentation is hypopigmentation. Classically, this is more common in phenol-based peels. Phenol is thought to eliminate the melanocyte's ability to produce melanin. This can be much more noticeable when single facial subunits are peeled. Hypopigmentation occurred with much greater frequency in the past with the Baker formulation and postoperative occlusive taping or thymol iodide masks. The concentration of the phenol and croton oil, the skin type, and taping are all factors contributing to the risk of hypopigmentation. This complication is irreversible. And patients should be counseled regarding the possible need for makeup use.

CONCLUSION

With the advent of CO_2 laser resurfacing, followed by erbium: YAG laser resurfacing, chemical peeling was marginalized as an outdated practice, supplanted by technologic advances. As well, phenol–croton oil peeling was considered a deep, dangerous peel that had an all-or-none effect at best and a peel riddled with complications at worst. Much like the outdated posits of Adolph Brown and his contemporaries, neither of the aforementioned sentiments is farther from the truth. Chemical peeling should be considered the standard as it is an effective and safe tool for the facial cosmetic surgeon. Furthermore, with our relatively new understanding of the role of croton oil, the modified phenol–croton oil peeling formulations offer a tool that can be tailored for different skin types, skin thicknesses, and rhytid depth. A thorough understanding of this peel will greatly expand the options of what a practitioner can offer his resurfacing patients.

HIGHLIGHTS

- Phenol peels the skin more deeply with increased concentrations, and the resultant peel is deeper with increasing concentrations of croton oil.
- The dilution of croton oil, in a constant phenol concentration, shortens the healing time and suggests a more shallow depth of penetration.
- Hetter peels allow for different depths of peeling for individual subunits of the face by varying concentrations of croton oil for individual facial subunits.
- The depth of the peel is dependent upon the amount of solution on the cotton tip, the uniform application of the solution, as well as the number of applications.
- Experience reveals that 0.8% croton oil Hetter solution works well in areas of deeper rhytids and thicker skin, such as the perioral, glabellar, and lateral periorbital areas.
- Intermediate areas should be treated with 0.4% croton oil Hetter solution such as the inferior periorbital area.
- A simple 88% USP phenol solution is used for all other areas to even the appearance.

194 Lasers in Facial Plastic Surgery

William Russell Ries *Joseph E. Hall*

"The Quantum Theory of Radiation," published by Einstein in the early 1900s, established laser theory. Maiman built the first laser in 1960, and patient treatment began shortly thereafter (1). The first cutaneous laser treatment with ruby and neodymium pulsed laser systems was performed by Goldman, and Patel subsequently developed the first CO_2 laser in 1964 (2). Lasers have become an integral treatment option for multiple disease processes, and clinical applications for lasers are ever expanding with the concurrent development of imaging systems, computer technology, and robotics (3). Lasers have become increasingly easy to use, and the fundamentals of laser physics are taught to a myriad of health care providers.

In this chapter, laser biophysics, laser–tissue interactions, technical aspects of laser treatment, and complications associated with lasers in facial plastic and reconstructive surgery are discussed. It is the hope of the authors that this chapter will provide a detailed understanding of laser technology, common laser applications, indications and reasons for employment of specific lasers, and practical knowledge related to the technical aspects of laser treatment.

LASER BIOPHYSICS

LASERs (*l*ight *a*mplification by the *s*timulated *e*mission of *r*adiation) produce light energy that travels in a waveform. The distance between two successive peaks of the wave corresponds to the wavelength, while the height of the peak of the wave corresponds to the amplitude. The amplitude is related to the intensity of the light. The period, or the time for the completion of a full wave cycle, is referred to as the frequency (4).

To produce this waveform, lasers follow the fundamentals of quantum mechanics. Specifically, a power source provides energy to a system. Subsequently, photons, units of light energy, present in the system strike atoms in the laser medium and can raise one of its electrons to a higher energy level. Either spontaneous or stimulated emission can occur at this point. Spontaneous emission occurs when the atom in the excited and unstable state reemits a photon and the electron returns to the lower energy level. If an atom in the higher energy state is struck by an additional photon, two photons are emitted. This process is termed stimulated emission (Fig. 194.1). The photons produced will continue to propagate the energy transfer via mirrors within the system. The photons emitted characteristically have the same wavelength, progress in the same direction, and travel in phase (3).

Lasers consist of four main components including a power source, a laser medium, an optical cavity or resonator, and a delivery system (Fig. 194.2). Electrical, light, and high-energy radio frequency waves are examples of possible excitation mechanisms. The optical cavity or resonator contains a medium that may be solid, liquid, gas, or a semiconductive material. Lasers also have a mirror that is 100% reflective and a mirror that is partially transmissive to allow energy to escape the chamber. Delivery systems are variable with most utilizing a fiberoptic delivery system but some using an articulated arm system (CO_2 laser).

The components of the laser together produce light that is of one wavelength (monochromatic), with little divergence (collimated), and in identical temporal and spatial phases (coherent). These properties differentiate laser light from ordinary light.

LASER–TISSUE INTERACTION

Laser energy can have a variety of effects on tissue ranging from activation of biochemical substances or stimulation of biologic tissues at low energy to coagulation or vaporization of biologic tissues at high energy (Fig. 194.3) (3). Most clinically relevant lasers utilize the thermal effects of lasers to coagulate or vaporize. The effect of a laser on a given

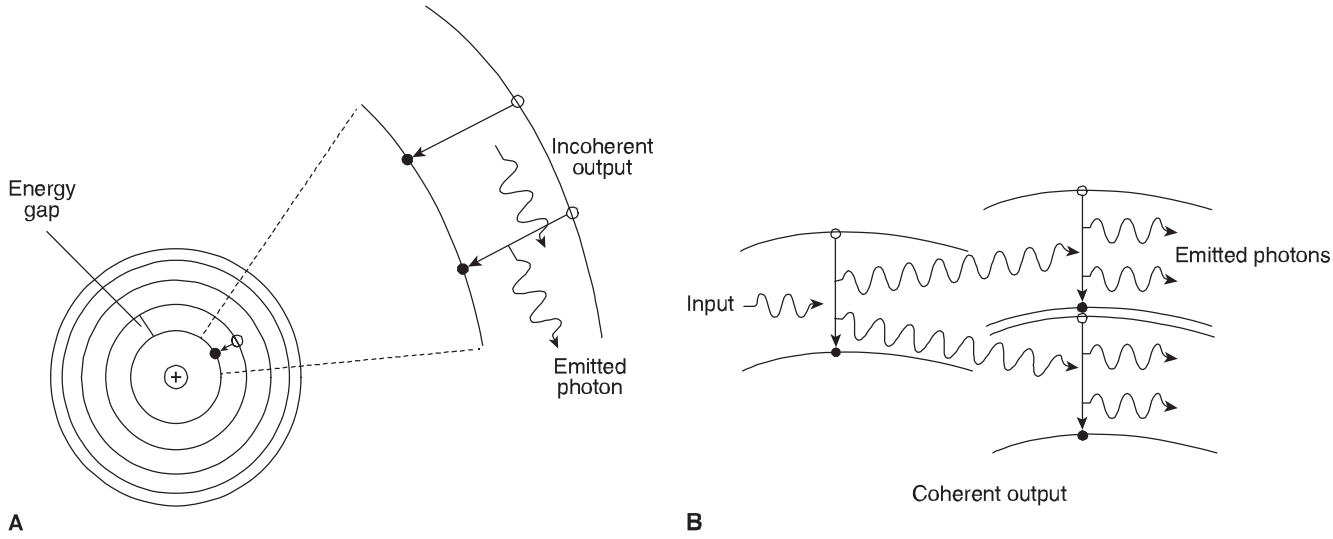

Figure 194.1 The processes of spontaneous and stimulated emission of radiation. (Reprinted from Papel ID, Frodel JL. *Facial plastic and reconstructive surgery*, 3rd ed. New York: Thieme, 2009:100, with permission.)

tissue is a function of the laser wavelength; laser energy density; and the amount of reflection, scatter, absorption, or transmission of energy that occurs (Fig. 194.4) (3).

Chromophores are substances that absorb energy at specific wavelengths. The specific absorption patterns of tissues partly determine the most efficacious laser for a given lesion. The chromophore absorbs light energy, which is then converted to heat. Coagulation of tissues occurs at 60°C to 70°C, and tissue vaporization occurs at 100°C (5). Appropriate laser selection allows for targeted thermal damage in tissues that absorb a specific wavelength of light. This process is termed selective photothermolysis (5). For example, the soft tissues of the body, which consist of mainly of water molecules, absorb CO_2 laser energy efficiently, whereas bone, with little water content, does not. Another important laser property is wavelength, with deeper tissue penetration occurring with longer wavelengths of light (5). The peak absorption wavelength for oxyhemoglobin, which is found in high concentrations in vascular malformations and hemangiomas, is 577 to 585 nm.

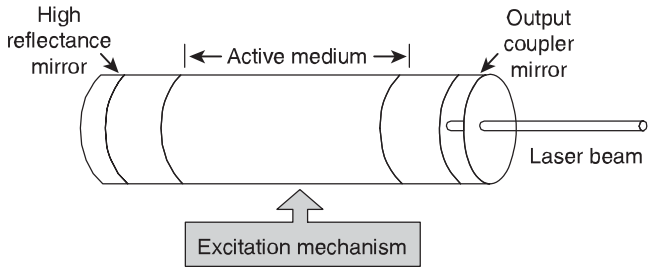

Figure 194.2 Laser apparatus. Lasers use a power source to provide light energy to a system, while photons produce stimulated emission of radiation. (Reprinted from Papel ID, Frodel JL. *Facial plastic and reconstructive surgery*, 3rd ed. New York: Thieme, 2009:100, with permission.)

Two important laser parameters are energy density and power density. Energy density (fluence) is a function of the power density (intensity) of the laser and the time of exposure. Power density is a function of the power divided by the cross-sectional area of the laser beam (spot size). Thus, by altering power density or time of exposure, the amount of energy delivered by a particular laser can be altered. Additionally, by decreasing the laser spot size, power density is increased.

$$\text{Energy density (fluence)} = \text{Power density} \times \text{Time}$$

$$\text{Power density} = \text{Power (watts)}/\text{Cross-sectional area of laser beam (spot size)}$$

Based on these equations, one can readily deduce that by decreasing the spot size of the laser beam, the power density to the tissue of interest increases. Pulsed energy can also be utilized to alter tissue effects. The pulsed energy mechanism incorporates regular periods of irradiation (on period) with alternating periods of no irradiation (off period). This alternating delivery of laser energy permits heat dissipation during the off period. Thus, thermal heat damage to surrounding tissue is minimized, particularly if the off period is longer than the thermal relaxation time of the tissue of interest. The thermal relaxation time is defined as the amount of time required for an object to dissipate half of its heat. The duty cycle is defined as the ratio of the on interval to the on plus off intervals.

Several pulsed modes have been created for use with lasers. Shuttering can block the delivery of a beam of laser light for specified intervals of time. Superpulse mode refers to a mechanism in which energy is stored during the off period and released during the on period. Q-switched lasers function by storing energy during the off period and releasing high-energy bursts of light for short time intervals using an electro-optical shutter (3). Ultimately, one

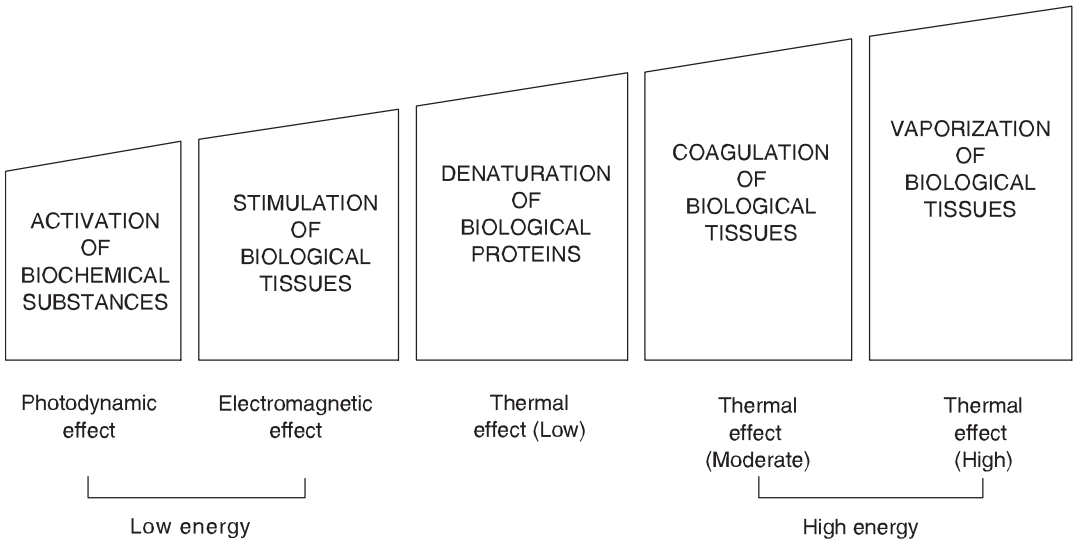

Figure 194.3 High-energy laser treatment causes vaporization and coagulation of tissues, while low-energy causes activation and stimulation of biologic tissues. (Reprinted from Papel ID, Frodel JL. *Facial plastic and reconstructive surgery*, 3rd ed. New York: Thieme, 2009:101, with permission.)

must match the laser wavelength, spot size, energy density, power, and duration of action to the tissue of interest and the desired outcome (5).

LASER CHARACTERISTICS

Flashlamp-Excited Dye Laser

The flashlamp-excited dye laser (FEDL) was designed for the treatment of vascular cutaneous lesions. The laser medium is a rhodamine dye, which is excited optically by a flashlamp. It is delivered by a fiberoptic carrier. This laser produces visible, yellow light (6). The FEDL system is frequently used to treat hemangiomas, port-wine stains, rosacea, and telangiectasias as it emits wavelengths of 585 nm, near the absorption peak of oxyhemoglobin (577 nm) (6,7). The FEDL has a dynamic cooling device that reduces the risk of epidermal injury.

The FEDL has an interchangeable lens system that allows for spot sizes of 3, 5, 7, or 10 mm. The pulse is 450 μs. More recently developed FEDLs can produce longer wavelengths (595 to 600 nm) with spot sizes of 10 to 12 mm and higher peak fluence potentials. These alterations have allowed for more effective treatment of the deeper vessels found in hemangiomas and port-wine stains (6,8). Additionally, longer pulse durations of 1.5 to 40 ms have allowed for telangiectasia treatment without the development of significant purpura (6,8–11). The alterations to the FEDL have provided a treatment that has been shown to reduce erythema, decrease height, and improve texture in scars (12). A decreased rate of recurrence of hypertrophic scars has also been found with the FEDL (13).

Pulsed dye lasers (PDLs) have recently incorporated a unique pulse structure where each macropulse is subdivided into eight micropulses. This technology allows for single-pass treatment with delivery of higher total fluencies with less risk of purpura (14,15). Most patients develop variable erythema and/or purpura following PDL treatments, which may last for 7 to 10 days. Furthermore, patients may develop hyperpigmentation, hypopigmentation, or scarring (6).

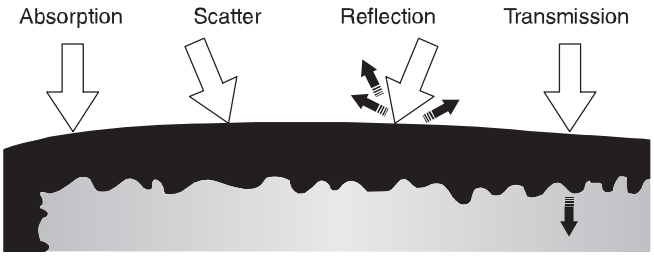

Figure 194.4 The biologic effect of a laser is partially dependent on the amount of absorption, scatter, reflection, or transmission of energy for a given tissue. (Reprinted from Papel ID, Frodel JL. *Facial plastic and reconstructive surgery*, 3rd ed. New York: Thieme, 2009:100, with permission.)

Intense Pulsed Light

Intense pulsed light (IPL) uses crystal filters to emit light with wavelengths of 590 to 1,200 nm. The light is noncoherent. The range of wavelengths and pulse durations capable of being produced by this laser are its primary advantages. Cutoff filters produce wavelengths that can be utilized for telangiectasias, skin discoloration, hair removal, or photoaging. Likewise, IPL system filters can eliminate shorter wavelengths to allow for greater dermal penetration with light of longer wavelength (6). IPL systems have also been used to treat port-wine stains and hemangiomas (6). In comparison with the PDL, IPL treatments require more time and have greater associated risks as additive heating occurs with successive passes and longer pulse durations (6).

The primary use for IPL systems is treatment of telangiectasias. Selected wavelengths between 470 and 1,400 nm corresponding to absorption peaks of oxyhemoglobin are used to specifically target vessels. The range of wavelengths allows for treatment of vessels at various depths and greater energy penetration into the tissue (6). Newer systems incorporate cooling with chilled sapphire windows.

Potassium Titanyl Phosphate Laser

The potassium titanyl phosphate (KTP) laser is a frequency-doubled (wavelength halved) Nd:YAG laser. This is accomplished by passing the laser energy though a KTP crystal. The resultant light is green with a wavelength of 532 nm, corresponding to a hemoglobin absorption peak. The penetration and scattering of this laser light is intermediate between the CO_2 laser and the Nd:YAG laser. The laser energy is delivered to tissue via a fiber. If the fiber is not in contact with the tissue, vaporization and coagulation occur. Lower settings are typically used for coagulation. If the fiber is in semicontact with the tissue, cutting occurs. The KTP laser has a wide range of pulse durations, from 1 to 100 ms. The KTP laser has a shallow penetration depth. Accordingly, there is low risk of purpura, edema, or crusting (6,16). Atrophic scarring is a concern with the KTP laser.

Red and Infrared Lasers

The alexandrite (755 nm), diode (800 to 940 nm), and Nd:YAG (1,064 nm) lasers are in the red and near-infrared (IR) range. These lasers have been used to treat reticular veins, port-wine stains, and deep vessels in vascular malformations. Red and IR lasers are effective for these lesions as they have wavelengths that target peaks of deoxyhemoglobin in the near-IR range (700 to 1,200 nm), achieve deeper penetration, and allow for higher fluence (6).

The alexandrite laser is a flashlamp-pumped solid-state laser in the red spectrum of light (755 nm) but is not visible. This laser is absorbed by melanin and achieves deep penetration. The alexandrite laser has been used with significant improvement in hypertrophic port-wine stains with settings of 3-mm spot size, fluence range from 30 to 85 J/cm^2, and dynamic cooling (17). Others use settings of 8-mm spot size for the initial treatment of deep malformations (6). Li et al. (18) also demonstrated the effectiveness of the long-pulse pulsed alexandrite laser for hypertrophic, purple port-wine stains. The authors did note that this laser can cause dyspigmentation but no scarring was noted (18). This wavelength is also absorbed by the blue and black pigments in tattoos and can be used for hair removal.

The diode laser uses superconducting materials that are directly coupled to fiberoptic delivery devices. These lasers result in varying wavelengths depending on the material used. Diode lasers are efficient, converting electrical power to light at efficiencies of 50%, which allows for less heat production and power input (16). The light is fiberoptically delivered.

The Nd:YAG laser emits a wavelength of 1,064 nm, in the near-IR spectrum. The laser medium is neodymium:yttrium aluminum garnet and uses a helium-neon aiming beam. Pigmented tissue is selectively targeted with this laser as it penetrates up to 4 to 6 mm for treatment of deeper vessels (19). The depth of penetration of the Nd:YAG is related to its scatter, which is much greater than with the CO_2 laser. Thus, the Nd:YAG laser can be used for deep vessel coagulation (~3 mm). Yang et al. found the long-pulsed Nd:YAG laser to be equally effective as the PDL for the treatment of port-wine stains in a series of 17 patients (20). The authors found that purpura lasted longer following PDL treatments, but the Nd:YAG caused greater perivascular and epidermal injury with scarring noted in one patient (20).

Depressed scarring and hyperpigmentation are potential complications associated with the Nd:YAG laser (6). Cooling devices assist in minimizing these risks. In comparison with the near-IR diode laser, the Nd:YAG laser has deeper penetration, incurs less surrounding epidermal injury, and may be used more safely in darker pigmented individuals (6).

Carbon Dioxide (CO_2) Laser

The CO_2 laser uses CO_2 gas as a medium and has a wavelength of 10,600 nm. This wavelength is found in the mid-IR range and is absorbed by water. This laser is utilized for tissue with high water content given that it is absorbed well by water molecules. Effects are typically superficial due to minimal scatter and high absorption rates. This laser seals vessels up to 0.5 mm in diameter and nerve fibers.

A helium-neon aiming beam is utilized with this laser system as the laser beam is invisible. Typically, the beam is delivered to tissue through mirrors and lenses in an articulated arm either by a handpiece or attached to an operating microscope (4).

Recently, the fractionated CO_2 laser has gained popularity as it provides several distinct advantages over traditional CO_2 laser treatments. The fractionated CO_2 laser employs the concept of fractionated photothermolysis, which spares the epidermis from significant injury while causing coagulative injury in the dermis (21). Injury to the surrounding tissue is minimized as the fractionated laser delivers microthermal zones that allow for rapid reepithelialization at the periphery. The fractionated CO_2 laser decreases scarring, hypopigmentation, and the recovery time of traditional CO_2 laser treatments (21,22). The fractionated CO_2 laser has been used to treat scars, rhytids, and photodamage (21).

Argon Laser

The argon laser has a range of wavelengths from 488 to 514 nm in the visible spectrum. The resonating chamber and laser medium create a band of wavelengths emitted from this laser. Filters can be used to limit the resultant

wavelengths emitted. Hemoglobin absorbs argon laser energy well, thus allowing for use in vascular lesions. A fiberoptic carrier represents the delivery system (4).

Continuous Yellow Dye Laser

The continuous-wave yellow dye laser produces a wavelength of 577 nm in the visible spectrum. The dye is excited by an argon laser. This laser is delivered by a fiberoptic cable. Shutters or a Hexascanner handpiece can pulse the light that is emitted. This laser is well suited for treatment of benign vascular lesions on the face.

Copper Vapor Laser

The copper vapor laser produces two wavelengths of the visible spectrum including a pulsed green light at 511 nm and a pulsed yellow light at 578 nm. A handpiece can deliver the light fiberoptically at spot sizes from 150 to 1,000 μm. This laser also is used to treat benign vascular lesions on the face as well as freckles, nevi, or keratoses.

LASER APPLICATIONS

Treatment Options

Treatment of lesions of the face has been revolutionized with the development and advancements in laser technology. When considering appropriate management for each patient and individual lesions, one must consider all available options. Common nonlaser treatment options consist of observation, ligation, excision, cautery, sclerosant therapy, chemotherapy, radiation, steroid therapy, embolization, systemic medications, or a combination of treatments. However, laser technology remains a mainstay in the treatment of facial lesions as laser selection often allows for targeted and selective photothermolysis. Throughout the discussion below regarding laser applications, treatment options will be further delineated in relation to specific lesions.

Vascular Lesions

Advances in medicine have provided understanding of the biologic basis for many vascular anomalies. Treatment of vascular lesions has evolved at a rapid pace with increasing knowledge of pathophysiology and technical advancements. One of the greatest strides in the treatment of vascular lesions came with the development of the laser.

While the original classification schema for vascular lesions has undergone necessary changes with advancements in the understanding of underlying pathophysiology, vascular lesions continue to be categorized based on structural components and biologic behavior. The general term "vascular lesion" refers to vascular malformations and hemangiomas.

Vascular malformations are differentiated from hemangiomas based upon their presence at birth, increasing size with patient growth, and normal rate of endothelial cell growth. Additionally, capillary vascular malformations have a propensity to become darker in color and develop surface thickening with time. Vascular malformations are often subclassified based on their vessel components: arterial, capillary vascular malformations (port-wine stains), venous, lymphatic, and/or combination lesions. Finally, vascular malformations characteristically have large ectatic vessels and lack endothelial hyperplasia.

In contrast, hemangiomas behave in a similar manner as true neoplasms. Hemangiomas have a proliferative phase with rapid growth and endothelial proliferation, followed by an involution phase. Involution of these lesions is a slow process. Hemangiomas are characteristically absent at birth and demonstrate endothelial hyperplasia in ectatic vessels.

Technical Aspects of Laser Treatment

The ideal laser should have a wavelength that is selectively absorbed by the targeted lesion, minimal epidermal absorption to reduce the incidence of scarring, and a flexible delivery mode capable of pulsed delivery to apply energy consistently based on the thermal relaxation time of the tissue. Multiple lasers have been manufactured and are used for a variety of lesions based on the key laser characteristics discussed above.

Lesion Subtypes

Hemangiomas

Hemangiomas behave in a similar manner as true neoplasms. These lesions typically appear in the few weeks after birth and grow disproportionately with the infant (23). Hemangiomas are more common in Caucasians with a female to male ratio of 3:1. The proportion of all hemangiomas occurring in the head and neck region is 60%. It has been proposed that these lesions result from growth of placental cells transferred to the fetus *in utero* (24). Resolution of these lesions is approximately 50% by age 5 years, 70% by age 7 years, and 90% by age 9 years (25). Following involution of hemangiomas, 40% to 50% of children will have residual telangiectatic cutaneous vessels, fibrous-fatty tissue, or scarring (26). Hemangiomas are classified as superficial (capillary), deep (cavernous), or combined (capillary–cavernous).

Treatment of hemangiomas has recently been modified following numerous reports regarding the success of beta-blocker therapy for these lesions (27–29). Recent studies have demonstrated rapid and consistent therapeutic effects of beta-blockers on infantile hemangiomas (29). Buckmiller et al. treated over 30 patients with propranolol (2 mg/kg/d, t.i.d. dosing), and 97% of lesions displayed improvement in the quality of the hemangioma.

Side effects noted included somnolence (27%) and reflux (10%) (30). While hemangiomas typically undergo spontaneous resolution and have recently been treated with beta-blocker therapy, laser and surgical therapies continue to be utilized for hemangiomas that alter vital functions, demonstrate ulceration, or cause significant cosmetic disfigurement (31). PDLs have been utilized for superficial lesions to lighten the lesion, induce regression, and possibly halt growth (Fig. 194.5) (5,32). Early studies found that PDL treatment possibly prevented enlargement and promoted involution. However, recent studies have called into question the ability of PDL to alter the natural course of hemangiomas. For example, a randomized controlled study by Batta et al. (33) found that PDL treatment versus observation in early hemangiomas resulted in similar clearance or residual signs of hemangioma at 1 year. This study also found that PDL treatment increased the likelihood of skin atrophy ($P = 0.008$) and hypopigmentation ($P = 0.001$) compared with observation (33). Additionally, other studies have noted that early PDL treatment may not decrease deeper hemangioma growth. The KTP and argon lasers can also be used for hemangiomas due to their photocoagulation selectivity.

The 1,064-nm Nd:YAG laser has been used effectively for deeper hemangiomas that failed to respond to other methods of treatment. Clymer et al. (34) treated children with hemangiomas with the 1,064-nm Nd:YAG laser using an interstitial technique and found a reduction in size of lesions and achieved good results without lesion reexpansion (Fig. 194.6).

Combined treatment using both the PDL and the Nd:YAG laser can be utilized for hemangiomas with both superficial and deep components. The Nd:YAG laser is often initially used to treat the deep component percutaneously. Settings typically include a 600-μm bare fiber, 10 to 20 J, and 0.5 to 1.0 pulse width. Ultimately, the settings of each laser type depend on the manufacturer and the specific laser utilized. Lesions are treated in a radial fashion to spare the overlying skin and deeper structures. These treatments may be repeated every 6 to 8 weeks. Once the bulk of the lesion is satisfactorily decreased, the superficial component may be treated with a PDL. Swelling should be expected postoperatively.

Capillary Malformations (Port-Wine Stains)

Port-wine stains (congenital capillary vascular malformations) are benign lesions within the dermis that are usually present at birth. Port-wine stains are present in approximately 0.3% to 0.5% of the population with 5% of these lesions associated with Sturge-Weber syndrome or Klippel-Trenaunay syndrome (3). These lesions are flat and pink to red in color. With age, these lesions can become darker and thicker with increased nodularity. The most common location for port-wine stains is the V_2 distribution of the face. While these lesions are typically not life-threatening, capillary malformations have been found to have significant

Figure 194.5 **A:** Right lateral nasal hemangioma, pretreatment. **B:** Appearance following FEDL treatments of hemangioma.

Figure 194.6 **A:** Left lower lip and buccal hemangioma, pretreatment. **B:** Posttreatment appearance following multiple Nd:YAG laser treatments with serial excisions over 2.5 years.

psychological consequences. Troilius et al. (35) found that port-wine stains negatively affected the lives of 75% of 259 children with these lesions. Additionally, earlier age at treatment has been associated with improved response rates.

The first treatment popularized for port-wine stains was the argon laser (488 to 514 nm). With limited penetration (0.1 mm), significant melanin absorption, and development of blistering and scarring, this treatment has largely been abandoned. Currently, PDLs with wavelengths between 585 and 595 nm are utilized. Treatment response is dependent on location, color, skin type, and age of patient (5). Two types of lesions have been described: type 1 have ectasias of the capillary loops and have a better response to PDL, while type 2 have dilated ectatic vessels in a ring pattern in the superficial horizontal plexus and demonstrate a poor response to PDL treatment. Treatment of port-wine stains with the PDL is effective with two passes per treatment with first pass settings of 5 to 6 J/cm^2, pulse width of 0.5 ms, and a spot size of 10 mm and second pass settings of 0.5 to 1.0 J/cm^2, pulse width of 2.0 ms, and a spot size of 10 mm. Cooling devices should be used with all treatments (5). PDL with epidermal cooling has also been used with pulse durations from 0.45 to 3 ms (5,6). Port-wine stains usually require multiple treatments repeated approximately every 2 to 3 months (Fig. 194.7). Ho et al. (36) performed a study with PDL or Nd:YAG treatment of port-wine stains on 107 Chinese patients and noted that 6.1 treatments were necessary for maximal lesional resolution. Additionally, Chan et al. (37) performed a study on port-wine stain treatment with Nd:YAG on 22 Chinese patients and noted that this treatment was only partially effective. The copper vapor laser and continuous dye laser have also been used for the treatment of port-wine stains (38,39). IPL treatment has been used with success in port-wine stains although most believe that patients with port-wine stains respond better to PDL treatment.

Venous Malformations

Venous malformations are treated when causing pain or functional problems (5). Treatment of these lesions typically consists of Nd:YAG laser (1,064 nm) therapy. Previous treatment options consisted of sclerotherapy, compression, or surgical resection. Treatment of these lesions can occur intralesionally or superficially (5). The Nd:YAG laser allows for deep vessel coagulation with penetration up to 4 mm. Superficial cooling is used to limit epidermal damage.

The main goal of treatment is to reduce bulk and improve contour. Settings that have been found to be effective for lesions with traceable vessels from 1 to 3 mm in diameter include a 6-mm spot handpiece, 80 J/cm^2, 50 ms pulse width, and frequency of 1 Hz (5). For vessels less than 1 mm, settings that have been utilized include a 3-mm spot handpiece, 150 J/cm^2, and 30 ms pulse width (5). Treatment of these lesions can occur at the earliest 8 weeks following previous treatment. Good results have been noted with Nd:YAG treatment of venous malformations (5,40). Care must be taken with Nd:YAG laser treatment of venous malformations as hypopigmentation, scarring, blistering, or burns can occur. Sclerotherapy for the deep vessels can be combined with laser treatments for the superficial vessels (5).

Telangiectasias

Telangiectasias are dermal lesions characterized by small ectatic vessels. A variety of subtypes have been described including linear, arborizing, punctuate, and spider (nevi or angiomas). The development of telangiectasias is thought to be related to estrogen, nasal trauma, surgery, and genetic susceptibility.

Facial telangiectasia treatment is based on selective thermolysis of oxyhemoglobin. Common lasers used for these lesions include the 595-nm PDL, 532-nm KTP laser, and 520-nm and 1,200-nm IPL (6). Other lasers used include the copper vapor laser and continuous-wave yellow dye laser. Many surgeons use the PDL with pulse stacking and multiple pass technique with good results (41). Common

Figure 194.7 **A:** Pretreatment appearance of a right port-wine stain. **B:** Clinical response of this lesion following multiple FEDL treatments over a 1-year period. Note the decreased size and discoloration.

settings for the PDL for telangiectasias include 10-mm spot size, fluences of 6.5 to 7.5 J/cm^2, and pulse duration of 6 to 10 ms (6). KTP laser treatment has been utilized for telangiectasias with surrounding erythema with single-pass treatments using 10-mm spot size, 20 to 30 ms, and fluences of 7 to 10 J/cm^2 (6). Smaller spot sizes are used for smaller lesions. IPL devices with wavelengths of 520 to 1,200 nm have also been used for telangiectasias. Epidermal cooling and evaluation of skin pigmentation are important for the successful application of this laser. Given the melanin absorption, hypopigmented patches and blistering can be side effects of using this laser on tanned or greater pigmented skin without selective filter utilization (6,42).

Generally, when treating telangiectasias, one should use the smallest spot size and lowest power that will obliterate the dilated vessel. This will avoid nonselective, surrounding tissue damage. Treatment ensues by tracing vessels until the dilated vessel disappears. Spider telangiectasias are treated by obliterating the periphery of the radial vessels and moving toward the center with treatment of the central vessels last (3). Treatment of telangiectasias usually occurs at a lower energy density than that needed for treatment of port-wine stains, and retreatment may occur 6 to 8 weeks following previous treatment.

Hereditary Hemorrhagic Telangiectasia

Hereditary hemorrhagic telangiectasia (HHT, Osler-Weber-Rendu syndrome) is an autosomal dominant disease that causes telangiectatic lesions on the skin and mucous membranes. Patients with HHT often experience epistaxis (~90%) and/or bleeding from lips, gingiva, tongue, buccal mucosa, or hard palate. Patients with this disease may also have arteriovenous malformations in the lungs or brain (43). On histologic examination, ectatic vessels are observed with incomplete surrounding muscular layers.

Septodermoplasty has been utilized, sometimes in combination with lasers, to treat severe epistaxis (44,45). Lasers utilized to treat HHT have included CO_2, argon, Nd:YAG, and KTP. Given its superficial effects and vaporization of the overlying mucous membrane, the CO_2 laser is not the ideal choice for patients with HHT. Argon and KTP lasers provide for vascular selectivity for this disease process. Additionally, the deeper penetration of the Nd:YAG laser allows for effective coagulation of the lesions in HHT (46). Treatment of these lesions is typically performed with a free fiber that is held above the mucosal surface, and the lesion is treated in a rosette fashion by encircling the central portion and subsequently coagulating the central lesion. Nd:YAG treatment generally consists of a power setting of 10 to 25 W with an exposure time of 0.5 seconds. KTP treatment generally consists of a power setting of 6 W with an exposure time of 0.5 seconds with a slightly defocused beam.

Pigmented Lesions

Pigmented lesions can include benign lentigines, freckles, café au lait spots, congenital nevi, melasma, or tattoos. It is unclear how lasers produce pigment destruction but it

is believed that photoacoustic damage to the cell by heating and expansion of melanosomes occur causing pigment breakup with phagocytosis and clearing.

Lasers often used to treat pigmented lesions include the pulsed dye (510 nm), copper vapor (511 nm), frequency-doubled Q-switched Nd:YAG (532 nm), KTP (532 nm), Q-switched and long-pulsed ruby (694 nm), Q-switched and long-pulsed alexandrite (755 nm), and Q-switched Nd:YAG (1,064 nm). The PDL is effective for lentigines, freckles, café au lait spots, and bright tattoo pigments such as red, purple, or orange. The ruby laser is preferentially absorbed by melanin and has a deeper level of penetration for effective treatment of the dermis. The Q-switched ruby laser is often used for removal of amateur blue-black tattoos. Red tattoos and other pigmented lesions are often removed with the frequency-doubled Q-switched Nd:YAG laser. The Q-switched alexandrite laser, with deeper penetration, is often used for pigmented lesions, lentigines, café au lait spots, and freckles. This laser can also be used to remove blue and green tattoos. In a previous study, it was shown that lentigines in dark-skinned patients responded better to long-pulsed 532-nm Nd:YAG laser treatment than Q-switched Nd:YAG laser treatment (47). The KTP laser is effective for solar lentigines and photoaging although darker skin types have been shown to have a higher side effect profile (48). Tattoo removal generally requires 5 to 10 treatments, while superficial lentigines and freckles can often be treated once.

Hair Removal

Lasers allow for effective although not permanent hair removal with less pain than electrosurgical techniques. The results of laser hair removal typically outlast traditional techniques including shaving, waxing, plucking, or electrolysis. Laser hair removal is much more effective on hair in the growth or anagen phase. Lasers with wavelengths between 690 and 1,100 nm, to target melanin, are primarily used for hair removal. The lasers often utilized are the red-light, IR, and filtered flashlamp IPL lasers. In removing hair, the pulse width of the laser roughly approximates the thermal relaxation time of the tissue (~10 to 100 ms) to adequately heat the targeted follicles. Cooling systems are used to limit the injury to surrounding areas.

The long-pulsed ruby laser (694 nm), long-pulsed alexandrite laser (755 nm), diode lasers (800 nm), filtered flashlamp IPL, and the Nd:YAG laser (with a carbon suspension) have been used for the process of hair removal. Several of these lasers have been shown to remove hair temporarily and provide long-term hair reduction, although multiple treatments are typically necessary for permanent results to be achieved (49,50). Dark-haired, light-skinned individuals typically have the best results with laser hair removal. Patients with darker skin colors are at a higher risk for hypopigmentation and have been shown to be more safely treated with longer wavelength lasers (51). A new technique that provides skin cooling with longer-pulse width laser treatments has increased the efficiency and decreased the side effects experienced by patients with darker skin colors during hair removal (52,53).

Skin Resurfacing and Rejuvenation

Lasers allow for skin resurfacing and rejuvenation in a controlled and reproducible manner. The water chromophore is targeted by the lasers used for this purpose. Vaporization is typically achieved in skin at approximately 5 J/cm^2 delivered in less than 1 ms. Lasers for skin resurfacing and rejuvenation are typically used for patients with rhytids, photoaging, and scarring.

CO_2 and erbium lasers are typical choices for resurfacing procedures. High-energy, short-pulsed systems with single pulses of 600 ms duration with fluences of 5 to 7 J/cm^2 have been used with the CO_2 laser. These systems minimize thermal damage. Another system utilizes scanning technology. With this system, a continuous laser beam with a microprocessor-controlled scanner moves the beam across the tissue to limit the dwell time at any point. Typical fluences are 5 to 15 J/cm^2 for this system. Erbium lasers rapidly ablate tissue with little thermal effect and cause less tissue shrinkage and faster reepithelialization. The CO_2 laser has also been used effectively for laser-assisted blepharoplasty (54). Rejuvenation of skin is often performed with IPL, PDLs, and Nd:YAG lasers (55–59). Shorter wavelength lasers have been shown to be better for the vascular and pigmentation effects from photoaging, while longer wavelength lasers are more effective for wrinkles (60). More recently, the fractionated CO_2 laser has been employed for laser resurfacing with improved results and less side effects than traditional CO_2 laser treatments (21). To achieve desired results, appropriate perioperative care, skin preparation, herpes prophylaxis, and local anesthesia are important. A pink color occurs following removal of the epidermis, a gray color indicates the papillary dermis, and a chamois yellow color indicates the reticular dermis.

Rhinophyma is a disease characterized by hyperplasia of the sebaceous glands and connective tissue. Most physicians use the CO_2 laser (5 to 10 W, continuous mode) for treatment of this disease. This laser allows the surgeon to sculpt the nose with precise excision and ablation of the tissue. Hemostasis is achieved with this laser and postoperative pain is minimal. The large nodules of rhinophymatous tissue are excised, and a defocused laser is then used to ablate the remainder of the lesion in a paintbrush style (Fig. 194.8).

Cutaneous Malignancies

The CO_2 laser can be used to excise basal and squamous cell carcinomas. This laser allows for sealing of vessels 0.5 mm or larger in diameter in a defocused mode. This laser can also be used for flap elevation or undermining. Postoperative pain is also reduced as nerve endings are sealed during the procedure. Photodynamic therapy is innovative and combines light-sensitive drugs that are

Figure 194.8 **A:** Pretreatment appearance of rhinophyma. **B:** Posttreatment appearance of rhinophyma following CO_2 laser ablation and excision.

given intravenously and concentrate in skin and neoplasms with lasers in an attempt to destroy nonmelanoma skin malignancies.

Expected Results

Realistic goals should be outlined with the patient and/or guardian preoperatively. Often, treatment of facial lesions is not designed or even capable of achieving complete resolution, and this should be discussed prior to initiation of any therapy. Risks, benefits, and alternatives should also be discussed in a forthright manner. Outlining the expected goals and demonstrating previous/realistic outcomes with patient photographs can be helpful.

Complications and Management

Complications in laser surgery are primarily avoided by understanding laser physics, laser–tissue interactions, and selecting lasers for appropriate indications. Approved training and safety courses should be attended by all surgeons desiring to perform laser surgery. Additionally, common side effects including hyperpigmentation, hypopigmentation, blistering, crusting, milia, purpura, scarring, infection, and erythema can result from routine laser treatments and should be fully discussed with the patient and family preoperatively.

Radiation hazards can cause injury to the eyes or skin. Eye injury may occur via direct intrabeam viewing or reflected laser light (5,24). Lasers with wavelengths in the 400 to 1,400 nm range of electromagnetic radiation can cause retinal damage as a result of laser beam focusing on the retina (24). Wavelengths of less than 400 nm or greater than 1,400 nm can produce corneal injury (24). Goggles protecting against laser-specific wavelengths should be worn at all times by all individuals in the operating room. Eye protection for the patient is also necessary. The eyes of the patient are often protected by taping the eyelids in the closed position with nonflammable, non-melting tape and covering the eyelids with saline-moistened gauze (5). Aluminum foil is then used to cover the periorbital region (5). Additionally, metallic corneal protectors (instead of plastic) should be used when using lasers in the periorbital region. Furthermore, the patient should have saline-moistened towels draped over all exposed, uninvolved facial skin as misdirected or reflected laser energy can result in burns (5). These inadvertent burns can also be avoided by placing the laser in standby mode or turning off when not utilizing the machine.

Chemical hazards associated with laser are often related to the dyes used for the laser medium. These dyes should only be changed by servicing individuals. Secondary hazards associated with laser usage include fire, noise, and high-voltage irradiation. The risk of fire is reduced by using

moistened towels in the operative field and minimizing misdirected laser energy (5). Management of the side effects and complications associated with laser treatment should address the underlying etiology and typically includes symptomatic treatment.

CONCLUSIONS

Laser treatment in facial plastic surgery must be individualized for each patient. Lasers are often important for the targeted treatment of facial lesions. Lasers are selected based on the type of lesion, chromophore content of the tissue, desired biologic effect, and characteristics of the laser including wavelength and energy density. When a surgeon comfortably understands the interplay between lesion or disease pathophysiology and laser characteristics, appropriate treatment and improved patient outcomes can be achieved.

HIGHLIGHTS

- Appropriate treatment of facial lesions requires an understanding of the pathophysiology underlying the etiology of the lesion and knowledge of nonsurgical and surgical options.
- Lasers are important tools in the armamentarium of facial plastic and reconstructive surgeons and are often utilized for the treatment of facial lesions.
- Lasers can allow for targeted treatment of facial lesions and produce light that is monochromatic, collimated, and coherent.
- Lasers are selected based on the type of lesion, chromophore content of the tissue, desired biologic effect, and characteristics of the laser including wavelength and energy density.
- Continued advancements in laser technology have improved results of laser treatment of lesions of the head and neck.

195 Management of Benign Facial Lesions

Karen J. Sundby *John A. Zitelli*

Successful management of facial lesions depends on accurate diagnosis, knowledge of natural history, and use of a specific appropriate treatment. A functional classification scheme, together with history and physical examination, allows narrowing of diagnostic possibilities. Most benign facial lesions are noninflammatory, including various tumors, cysts, and melanocytic lesions (Table 195.1). Important exceptions include specific infectious, degenerative, and metabolic conditions that clinically appear and behave as inflammatory disorders (e.g., verruca, molluscum contagiosum). "Benign" facial lesions can signal serious systemic diseases (Tables 195.2 to 195.4).

HISTORY AND PHYSICAL EXAMINATION

Important questions to ask relate to duration of lesion, family history, fluctuation in size or drainage of any material, rapidity of onset, pain (e.g., leiomyomas are often spontaneously painful), and associated physical findings (e.g., tuberous sclerosis). Inspection and palpation are aided by adequate lighting or side lighting. Diascopy (pressing a clear microscope slide over the lesion to determine whether it is blood-filled—i.e., of vascular origin) also is useful. The lesion is classified by depth (epidermal, dermal, or subcutaneous) and other characteristics (cystic vs. solid; tenderness; color; texture; mobility; surface features, such as smooth or verrucous; presence of a central punctum), distribution and arrangement of lesions, and associated inflammation.

EPIDERMAL LESIONS

Epidermal lesions are most common, including seborrheic keratosis, actinic keratosis, comedones, milia, cutaneous horn, and epidermal cysts (1–5).

Actinic keratosis (or solar or senile keratosis) is composed of small, usually multiple erythematous lesions on sun-exposed areas, such as the face, exposed scalp, and dorsum of the hands. They have a rough, adherent scale and are more easily felt than seen. Actinic keratosis can develop into squamous cell carcinoma (10% to 20%), which usually does not metastasize. The lifetime risk of squamous cell carcinoma in an individual with actinic keratosis has been estimated to be 6% to 10% (6,7).

An analogous lesion to an actinic keratosis, actinic cheilitis (Fig. 195.1), occurs on the lip's vermilion border. It presents with hyperkeratosis, erosions, and a dull opaqueness.

Cutaneous horns (Fig. 195.2) are hyperkeratotic conical lesions whose height is at least half their largest diameter. Various types of lesions may be present at their bases (actinic keratosis, verruca, squamous cell carcinoma, seborrheic keratosis, and rarely trichilemmoma or basal cell carcinoma). Cutaneous horns require adequate removal so their bases can be examined histopathologically (8).

Seborrheic keratoses have brownish-black, verrucous papules or plaques with a "stuck-on" appearance, reflecting their epidermal origin. The sign of Leser-Trélat, the abrupt appearance or explosive expansion in size and number of multiple seborrheic keratoses, especially if accompanied by pruritus, has been implicated as a cutaneous marker of internal malignancy (9,10). In black patients, they may appear on the face as multiple brown to black papules over the cheeks, called dermatosis papulosa nigra.

Epidermal cysts are often compressible and may have visible puncta. If they have been inflamed, they may be fixed to surrounding tissue. It may be difficult to tell epidermal cysts from lipomas or neurofibromas. Lipomas are soft and often lobulated, lack puncta, and are movable against overlying skin. Neurofibromas similarly lack puncta and often display "button-holing" (described later).

Milia are small, yellowish-white, 1- to 2-mm papules. Primary milia develop spontaneously, commonly in newborns and people who are predisposed to them. Secondary

TABLE 195.1 CLASSIFICATION OF BENIGNFACIAL LESIONS

Inflammatory lesions
- Xanthelasma
- Molluscum
- Verruca

Noninflammatory lesions
- Epidermal tumors and cysts
  - Seborrheic keratosis
  - Epidermal cyst
  - Milia
  - Dermoid cyst
  - Actinic keratosis
  - Keratoacanthoma
  - Comedones
  - Cutaneous horn
- Skin-appendage tumors
  - Trichofolliculoma
  - Trichoepithelioma
  - Pilomatricoma
  - Trichilemmoma
  - Nevus sebaceous
  - Sebaceous hyperplasia/rhinophyma
  - Hidrocystoma
  - Syringoma

Non–skin-appendage tumors
- Vascular
  - Hemangiomas (capillary, cavernous, flammeus)
  - Angiomas
  - Telangiectasias
  - Pyogenic granuloma
  - Venous lake
- Fibrous
  - Soft fibroma (skin tag)
  - Fibrous papule
  - Adenoma sebaceum (angiofibroma)
  - Hypertrophic scar/keloid
- Neural
  - Neurofibroma
- Fatty/muscular/osseous
  - Lipoma
  - Multiple miliary osteomas
  - Leiomyomas
- Melanocytic lesions
  - Nevi
  - Lentigines
  - Ephelides (freckles)
  - Nevus of Ota
  - Blue nevus
  - Spitz nevus

TABLE 195.2 DIFFERENTIAL DIAGNOSIS OF SYNDROMES ASSOCIATED WITH MULTIPLE BENIGNFACIAL LESIONS

Disease	Onset	Cutaneous Features	Systemic Features
Neurofibromatosis	Variable to adulthood, seven types	Neurofibromas Cafe-au-lait macules Axilliary freckling	Multiple skeletal, endocrine, and neurologic abnormalities; increased incidence of malignancy (Wilms, CNS/PNS rhabdomyosarcoma, leukemia)
Tuberous sclerosis	Variable (early childhood to young adult life)	Angiofibromas (adenoma sebaceum, shagreen patches, periungual fibromas, ash leaf white macules)	Mental retardation, epilepsy, multiple organ hamartomas (eye, kidney, heart)
Gardner syndrome	May first appear at age 7–10, 50% display syndrome by age 20	Multiple epidermal cysts	Malignant degeneration (40%), osteomas of facial bones, fibromas, lipomas, leiomyomas of stomach or ileum
Muit-Torre syndrome	Variable	Sebaceous tumors of skin (most are adenomas) with or without keratoacanthomas (often very large)	Visceral neoplasms (often multiple, especially GI, larynx, endometrium)
Cowden disease	Variable	Multiple trichilemmomas, gingival fibromatosis	Greatly increased risk of breast carcinoma, thyroid adenomas, and carcinomas
Multiple endocrine neoplasia (type 2b)	Early childhood	Neuromas of oral and nasal mucosa, upper GI tract, and conjunctiva; lentigines; "blubbery" lips	Increased risk for medullary thyroid carcinoma, pheochromocytoma, marfanoid habitus, kyphoscoliosis

CNS, central nervous system; PNS, peripheral nervous system; GI, gastrointestinal.

TABLE 195.3 HEREDITARY TELANGIECTATIC SYNDROMES

Disease	Onset	Cutaneous Features	Systemic Features
Rothmund-Thomson syndrome	3 mo–2 y	Telangiectasias, mottled pigmentation, and atrophy (poikiloderma) of face, arms, legs, buttocks	Moderate dwarfism, sparse hair, cataracts, photosensitivity
Bloom syndrome	Infancy	Erythema and telangiectasias of butterfly area of face, forehead, ears, lids, hands, and forearms	Dwarfism, photosensitivity
Cockayne syndrome	Second year	Erythema and mottled pigmented scarring of butterfly area of face	Physical and mental retardation, loss of subcutaneous fat on face, Mickey Mouse ears
Hereditary hemorrhagic telangiectasia	Childhood	Punctate or linear telangiectasias of face, lips, ears, conjunctiva, upper trunk, arms	Mucosal hemorrhage
Ataxia-telangiectasia	3–5 y	Linear telangiectasias of conjunctiva, eyelids, ears, cheeks	Dwarfism, ataxia

A differential diagnosis also includes the collagen vascular diseases and liver diseases.
Modified from Champion RH, Burton JL, Burns AD, et al., eds. *Rook's textbook of dermatology*, 6th ed. London, UK: Blackwell, 1998, with permission.

TABLE 195.4 SYNDROMES WITH MULTIPLE MELANOCYTIC LESIONS

Disease	Onset	Cutaneous Features	Systemic Features
Neurofibromatosis	See Table 195.1	See Table 195.1	See Table 195.1
Albright syndrome	Melanotic macules appear soon after birth.	Melanotic patches (unilateral)	Polyostotic fibrous dysplasia, precocious puberty, endocrine dysfunctions
Peutz-Jeghers	Hyperpigmented macules are usually present at birth or early childhood.	Melanotic macules of lips and oral mucosa	Degeneration (2%–3%) of granulosa cell tumors in females (20%), increased association of duodenal cancer
LEOPARD syndrome	Lentigines appear in infancy and increase in numbers.	Multiple lentigines	Ocular hypertelorism, pulmonary (Moynahan syndrome) stenosis, abnormalities of genitalia, growth restriction, deafness (neural)
Lamb syndrome	—	Facial and genital lentigines, mucocutaneous myxomas, blue nevi	Atrial myxomas
Name syndrome	—	Nevi, myxoid neurofibromata, freckling (ephelides)	Atrial myxoma
Centrofacial lentiginosis	Lentigines appear in first years of life.	Midfacial freckling, sacral hypertrichosis, fusion of eyebrows	High arched palate, missing upper incisors, seizures, mental retardation, scoliosis, spina bifida
Cronkhite-Canada syndrome	—	Melanotic macules on face, extremities, alopecia, onychodystrophy, hyperpigmentation	Gastrointestinal polyposis

LEOPARD, lentigines, electrocardiographic abnormalities, ocular hypertelorism, pulmonary stenosis, abnormal genitalia, retardation of growth, deafness.

Figure 195.1 Actinic cheilitis. (From Werner R. *Massage therapist's guide to pathology.* Philadelphia, PA: Lippincott Williams & Wilkins, 2012, with permission.)

milia may develop from trauma; from subepidermal blistering diseases, in areas of topical corticosteroid–induced atrophy; or postdermabrasion. In the latter case, the milia are probably a proliferative postinjury epithelial response.

Comedones superficially resemble milia but occur in specific situations. Open comedones (blackheads) are small (1- to 2-mm) papular lesions with a central black plug. They are usually multiple, occurring with acne vulgaris or actinically damaged skin. Closed comedones (whiteheads) are 1- to 2-mm white lesions seen with acne vulgaris. Histologically, comedones are dilated cystic hair follicles filled with keratinous and lipoid material.

SKIN-APPENDAGE TUMORS

Skin-appendage tumors have diverse clinical presentations. They are common on the face and scalp because of the numerous appendageal structures there.

Many facial appendage tumors are small skin-colored papules. Trichofolliculomas occur in adults as solitary facial lesions. They have a central pore with a white wool-like tuft of hair, a diagnostic feature.

Trichoepitheliomas are also small, flesh-colored papules. They are solitary or multiple. Multiple lesions are autosomal dominant, first appearing in childhood, with the number of lesions gradually increasing. Multiple trichoepitheliomas cluster around the central face and can occur with cylindromas, another benign appendage tumor often occurring on the scalp. These can grow together, resembling a turban (turban tumor). At times, trichoepitheliomas can be confused with basal cell carcinomas, both clinically and pathologically.

Trichilemmomas are small, pink to brown facial papules, in solitary and multiple forms. The multiple form can be a feature of the multiple hamartoma syndrome or Cowden disease, an autosomal-dominant genodermatosis associated with a high incidence of neoplasms (both benign and malignant) of the breast and thyroid, which occur in up to two-thirds of patients (11). Multiple trichilemmomas occur in all patients with Cowden disease and precede development of breast cancer, allowing identification of women at risk. These lesions appear nonspecific or can resemble small verrucae. In Cowden disease, oral lesions appear as 1- to 3-mm skin-colored papules that can assume a subtle cobblestone appearance or be so extensive that they involve the entire oral cavity, including the tongue.

Sebaceous hyperplasia is a common papular lesion occurring in older people. It is composed of 2- to 3-mm yellow to orange lobulated papules with a slight central umbilication. They can be solitary or multiple, commonly on the forehead and nose (highest number of sebaceous glands). They are enlargements of normal sebaceous glands. They also can occur with cyclosporine use and can be a feature of acne rosacea (rhinophyma) (Fig. 195.3).

Syringomas are small, flesh-colored to translucent papules that are intraepidermal eccrine duct adenomas. A syringoma may occur at any site on the body but are prone to occur in the periorbital area, especially the eyelids.

Figure 195.2 Cutaneous horn. (From Goodheart HP. *Goodheart's same-site differential diagnosis: a rapid method of diagnosing and treating common skin disorders.* Philadelphia, PA: Lippincott Williams & Wilkins, 2010, with permission.)

Figure 195.3 Rhinophyma. (From Werner R. *Massage therapist's guide to pathology.* Philadelphia, PA: Lippincott Williams & Wilkins, 2012, with permission.)

Figure 195.4 Pilomatricoma. (From Lugo-Somolinos A, McKinley-Grant L, Goldsmith LA, et al. *VisualDx: essential dermatology in pigmented skin.* Philadelphia, PA: Lippincott Williams & Wilkins, 2011, with permission.)

Syringomas often have a predilection for apocrine areas (axillae, vulva) or eruptive forms on the trunk or in dermatomal patterns. The lesions are removed from women more commonly than men, although it is not entirely clear that this represents a gender predilection rather than biopsy selection bias resulting from cosmetic or social factors.

Hidrocystomas are small, uncommon cystic periorbital lesions, most commonly seen on the eyelid margin. They are 2 to 15 mm in diameter, with a translucent bluish quality. Apocrine hidrocystomas are larger and solitary, whereas eccrine hidrocystomas are smaller and multiple.

Pilomatricomas (Fig. 195.4) are tumors typified by follicular matrical cornification, usually presenting as a solitary, hard, deep-seated nodule, usually on the face or upper extremities. The nodules may have a faint bluish-red color and are sharply demarcated, ranging in diameter from 0.5 to 3.0 cm. They are common in children and young adults.

Nevus sebaceus (Jadassohn nevus; Fig. 195.5) is a hamartoma that exhibits follicular, sebaceous, and apocrine malformation to varying degrees (12). The lesion is a congenital lesion presenting as a solitary, often linear, slightly raised, orange-yellow hairless plaque on the scalp or face. Its morphologic appearance changes with the activity of underlying sebaceous glands by becoming more verrucous and nodular at puberty. It is well-established that nevus sebaceus may develop secondary adnexal neoplasms, most commonly benign but sometimes malignant. Trichoblastoma and syringocystadenoma papilliferum are the most commonly found benign neoplasm, whereas basal cell carcinoma is found in less than 1% of the cases (13–15). Patients rarely have extensive nevus sebaceus plaques with an associated neurocutaneous syndrome (epilepsy, mental retardation, skeletal deformities).

Figure 195.5 Nevus sebaceus. (Image provided by Stedman's.)

NON–SKIN-APPENDAGE TUMORS

Lesions derived from non–skin-appendage elements include vascular, fibrous, neural, fatty, muscular, and osseous tissues (1–4).

Vascular Tumors

Cherry angiomas are a very common, benign vascular proliferation found on most adults. They are bright-red, dome-shaped papules, 2 to 4 mm in diameter, most commonly found on the trunk and extremities. Patients usually bring these to the attention of the physician when they are chronically traumatized or cosmetically undesirable.

Vascular malformations include capillary malformations (port-wine stain), venous malformations (cavernous hemangioma), lymphatic malformations (lymphangioma, lymphangioma circumscriptum, cystic hygroma), and arteriovenous malformations. It is important therapeutically and prognostically to distinguish among these. Port-wine stains (capillary malformation) are often present at birth as large, flat, pink, well-demarcated patches that demonstrate a growth pattern that parallels the growth of the child. With age, the affected skin develops a more pronounced red color, thickens, and becomes more nodular. Various syndromes are associated with capillary malformations. Sturge-Weber syndrome is a sporadic neurologic disorder in which a facial capillary malformation (usually V1 distribution of the trigeminal nerve) is associated with ipsilateral ocular and leptomeningeal anomalies. When capillary malformations occur on an extremity, a progressive overgrowth of the affected extremity may occur with underlying osteohypertrophy and arteriovenous fistulae, which is known as Klippel-Trenaunay syndrome.

Capillary hemangiomas are more common in females and premature infants. They appear between the third and fifth weeks of life, grow for several months to 1 year, and then regress. Of capillary hemangiomas, 70% regress by age 7 years. Ultimately, only 6% are cosmetically problematic. Histologically, there is vascular endothelial cell proliferation.

The most common acquired hemangioma is a pyogenic granuloma, often found on the face and extremities. It is a rapidly growing, friable, solitary red papule or polyp that frequently ulcerates and easily bleeds. Pyogenic granulomas are often precipitated by minor trauma or pregnancy.

Figure 195.6 Osler-Rendu-Weber disease (hereditary hemorrhagic telangiectasia). (From Schaaf CP, Zschocke J, Potocki L. *Human genetics.* Philadelphia, PA: Lippincott Williams & Wilkins, 2011, with permission.)

Figure 195.7 Keloid. (From Halperin ECC, Perez CA, Brady LW, et al. *Perez and Brady's principles and practice of radiation oncology.* Philadelphia, PA: Lippincott Williams & Wilkins, 2007, with permission.)

The second major group of vascular lesions of the face are the ectasias, or dilatations of blood vessels (not new vessel growth). These include telangiectasias and venous lakes. Most are acquired or may have syndromal features (Table 195.3).

Facial telangiectasias are extremely common and consist of dilated capillaries that appear as tiny, red, cutaneous vessels that blanch when pressure is applied. Telangiectasias may present in a linear pattern or spider-like with a central feeding vessel and radiating dilated vessels. These lesions occur with conditions such as rosacea, scleroderma, dermatomyositis, radiation dermatitis, chronic alcoholism, liver disease, pregnancy, childhood, Osler-Rendu-Weber disease (Fig. 195.6), carcinoid syndrome, idiopathic telangiectasia (generalized essential telangiectasia), or actinic skin degeneration.

Venous lakes are deep-blue cutaneous nodules usually on the lips, ears, or face. Histologically, they are dilated venules in the dermis that blanch with compression.

Fibrous Tumors

Facial fibrous tissue tumors include skin tags, fibrous papules, adenoma sebaceum, hypertrophic scars, and keloids. A skin tag (soft fibroma) is the most common fibrous lesion. These are small (1 to 2 mm), smooth, filiform, flesh-colored growths commonly located around the eyes or on the neck. They are usually multiple, distinguished from verrucae by their smooth surface. Skin tags occur elsewhere on the body (particularly the inguinal folds and axillae) and can occur as large, solitary, bag-like structures on the lower trunk.

Fibrous papules are solitary, dome-shaped, flesh-colored papules located on the central face of adults, most commonly the nasal ala and alar crease. These can clinically simulate intradermal nevi, adnexal tumors, or basal cell carcinomas. Sampling biopsies are often done to exclude a basal cell carcinoma. Otherwise, these lesions are benign and do not require further treatment unless it is of cosmetic concern to the patient.

Hypertrophic scars can be confused with keloids. Both are red, raised, smooth, and shiny, but hypertrophic scars remain within the injury area, whereas keloids (Fig. 195.7) extend beyond the original injury site. Hypertrophic scars flatten over time, and keloids proliferate. There is familial and racial predilection (darker skin pigmentation) for keloid formation. Hypertrophic scars develop after wound infection or in certain anatomic locations (deltoid, angle of mandible, sternum). Keloids are uncommon on the face, even in keloid-forming individuals with the exception of the ears.

Adenoma sebaceum (Fig. 195.8) is an uncommon but characteristic feature of tuberous sclerosis. Adenoma sebaceum, mental retardation, and epilepsy form the classic triad of this dominantly inherited neurocutaneous syndrome. Adenoma sebaceum is a misnomer because these growths are not adenomas nor are they sebaceous. These growths are actually angiofibromas. They are numerous small, reddish, smooth papules symmetrically distributed around the nose, cheeks, and chin, sparing the upper lip. They first appear in late childhood, so they are a late sign of tuberous sclerosis.

Fatty/Muscular Tumors

Tumors of fatty, muscular, and osseous tissue occasionally occur on the face (1–5). The most common are lipomas. Clinically, lipomas are single or multiple, soft, rounded,

Figure 195.8 Adenoma sebaceum. (From McMillan JA, Feigin RD, DeAngelis C, et al. *Oski solution.* Philadelphia, PA: Lippincott Williams & Wilkins, 2006, with permission.)

lobulated growths that are freely movable against the overlying skin. These collections of mature fat cells with a thin connective tissue capsule must be differentiated from other soft, round growths such as neurofibromas and epidermal cysts.

Leiomyomas occur less commonly on the face. These small, firm, reddish-brown nodules arise from erector pili hair follicle smooth muscle. They are often multiple, arranged in a group or line, and painful.

Neural Tumors

Neurofibromas are benign nerve sheath tumors that can develop as solitary lesions or as multiple lesions as part of neurofibromatosis (NF1) (von Recklinghausen disease). Solitary neurofibromas are soft flesh-colored tumors that resemble normal nevocytic nevi. They may become pedunculated. When pressed, the tumor easily invaginates through a small skin opening (button-hole sign). Subcutaneous neurofibromas are either deep, firm, discrete nodules or, more characteristically, large, flabby, plexiform neuromas that feel like a bag of worms. The plexiform neurofibroma is especially important because it is considered pathognomonic of neurofibromatosis and requires proper patient management (16).

Melanocytic Tumors

Melanocytic nevi contain intraepidermal or dermal collections of nevus cells or both (1–5).

Melanocytic nevi are congenital or acquired and described by their histologic location of the nevus cells within the skin as either junctional, compound, or intradermal. Very few nevi are present at birth; therefore, most nevi are acquired and follow a specific life cycle. Most nevi appear in childhood, adolescence, or early adulthood, with few new nevi developing past middle adulthood. As age increases, the number of nevi progressively decreases. They pass through successive stages of junctional, compound, and intradermal development. Most nevi in children are junctional; in older adults, most nevi are intradermal.

Nevus appearance corresponds with histology. Junctional nevi (Fig. 195.9) are flat and pigmented; dermal nevi (Fig. 195.10) are flesh colored and dome shaped or pedunculated; compound nevi (Fig. 195.11) are in between. Congenital nevi are larger than acquired nevi, are pigmented and slightly elevated, and may have increased hair. Compared with acquired nevi, they have deeper nevus cell extension into dermis, distribution of nevus cells near cutaneous appendages, and extension of nevus cells between collagen bundles. Giant congenital nevi have an increased risk for malignant transformation (17,18), whereas small- and medium-sized congenital nevi have little or no increased risk for developing into melanoma.

Figure 195.10 Dermal nevi. (From Craft N, Fox, LP. *VisualDx: essential adult dermatology*. Philadelphia, PA: Lippincott Williams & Wilkins, 2010, with permission.)

Spitz nevus (epithelioid and spindle cell nevus) is a rare type of melanocytic nevus (Fig. 195.12). It is a solitary, well-circumscribed, dome-shaped papule or nodule varying in color from pink to tan to brown. Their size varies from about 2 mm to about 2 cm, and they occur on the face and extremities of children and young adults. Although benign, it can resemble malignant melanoma histologically and may require treatment as melanoma unless a definitive distinction of benign versus malignant can be assured by the pathologist.

The principal tumors of epidermal melanocytes are freckles (ephelides) and lentigines. These flat, pigmented lesions are distinct from seborrheic keratoses or junctional nevi, which they resemble. Actinically induced lentigines are lentigo senilis (Fig. 195.13), whereas randomly occurring ones are lentigo simplex. Most facial lesions are lentigo senilis. They are light to dark-brown flat lesions, 5 to 20 mm in diameter or larger. Most are benign, but occasionally on the face they are confused with malignant

Figure 195.9 Junctional nevus. (From the Institute for Dermatologic Communication and Education, 1976, with permission.)

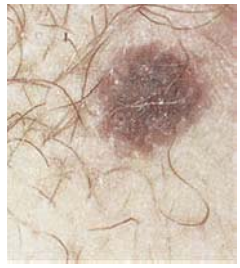

Figure 195.11 Compound nevus. (From Wilkinson EJ. *Wilkinson and Stone atlas of vulvar disease.* Philadelphia, PA: Lippincott Williams & Wilkins, 2013, with permission.)

Figure 195.12 Spitz nevus. (From Elder AD, Elenitsas R, Johnson BL, et al. *Synopsis and atlas of Lever's histopathology of the skin.* Philadelphia, PA: Lippincott Williams & Wilkins, 1999, with permission.)

lesions such as lentigo maligna or melanoma *in situ*. Other features distinguishing lentigines from freckles are onset later in life, lack of seasonal variation, and larger size. Psoralen and ultraviolet A photochemotherapy lentigines are lesions precipitated by ultraviolet A phototherapy with psoralen. Freckles, in contrast, are easily recognized as small, brown, scattered macules occurring on sun-exposed areas of fair-skinned people. They have no malignant potential, darken in response to sunlight, and develop in childhood. Multiple facial lentigines are a prominent feature of numerous syndromes (Table 195.4).

The main facial dermal melanocytic lesions are benign intradermal and compound nevi, as described earlier. Other less common lesions include nevus of Ota and common blue nevus. Nevus of Ota is a unilateral blue to brown pigmented patch involving the skin of the periorbital, temple, forehead, or malar areas that occurs predominantly in dark-skinned races. Usually, the ipsilateral sclerae (Fig. 195.14) are involved, and occasionally the conjunctiva, cornea, retina, and oral and nasal mucosa are involved. Nevus of Ota has two times of onset: early childhood before the age of 1 year and around puberty. Malignancies arising in nevi of Ota are rare but when present do not adhere to the typical ABCD rules of melanoma (19). Several cases of primary malignant melanoma of the choroid, orbit, iris, chiasma, and meninges have developed in association with nevus of Ota that exhibited eye involvement (20).

Figure 195.13 Lentigo senilis. (From Werner R. *Massage therapist's guide to pathology.* Philadelphia, PA: Lippincott Williams & Wilkins, 2012, with permission.)

Figure 195.14 Nevus of Ota. (From Craft N, Taylor E, Tumeh PC, et al. *VisualDx: essential adult dermatology.* Philadelphia, PA: Lippincott Williams & Wilkins, 2010, with permission.)

Common blue nevi are small (1 cm), smooth, dome-shaped papules (Fig. 195.15) with a characteristic blue appearance as a result of the presence of deep intradermal melanin pigment that is viewed through intact skin (Tyndall effect). The lesions may appear anywhere, but about 50% of cases are found on the dorsa of the hands and feet.

Infectious Lesions

Warts (verruca vulgaris) are composed of intraepidermal lesions resulting from local infection with the human papilloma virus (1–5). They occur at any age, are spread by local contact or autoinoculation, have an unpredictable course, and are usually asymptomatic. They are more common and resistant to treatment in patients who are immunocompromised.

There are more than 100 genotypes of human papilloma virus, including common, filiform, plantar (including mosaic), flat, and anogenital warts. They have an irregularly corrugated (verrucous) surface, with pinpoint black dots of thrombosed capillaries. On mucosal surfaces, they may be smooth-surfaced papules or on flexible, pedunculated stalks.

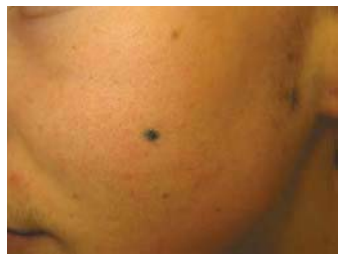

Figure 195.15 Blue nevus.

Figure 195.16 Flat warts. (From Burkhart C, Morrell D, Goldsmith LA, et al. *VisualDx: essential pediatric dermatology.* Philadelphia, PA: Lippincott Williams & Wilkins, 2010, with permission.)

Common warts are firm, sessile papulonodular growths, uncommon on the face. Filiform warts, common on the face, are tag-like protuberances resembling skin tags. Flat warts (Fig. 195.16) also are common on the face, particularly in young women, and can be missed if not viewed with side lighting. They are slightly elevated, light-brown, 1- to 5-mm grouped discrete lesions.

Molluscum contagiosum (Fig. 195.17) is a cutaneous infection caused by a poxvirus. It produces shiny, flesh-colored to pink, dome-shaped, firm papules with central umbilication. It is spread by local contact or autoinoculation and is common in children, sexually active young adults, and individuals who are immunocompromised. When central umbilication is not apparent, they resemble milia or closed comedones. In patients who are immunocompromised, these lesions can form large crateriform

Figure 195.17 Molluscum contagiosum. (From the American Academy of Dermatology, 1977, with permission.)

and plaque-like lesions involving large areas of the face. Molluscum lesions have a central expressible inclusion, which can confirm the diagnosis. In patients who are immunocompromised, disseminated deep fungal infections (e.g., *Cryptococcus*) are also part of the differential diagnosis.

LABORATORY STUDIES

Most dermatologic diagnoses can be made by inspection or skin biopsy (shave, punch, or excision) (2,21,22). A shave biopsy uses a scalpel blade to shave the lesion flush with, or slightly below, the surrounding skin (Fig. 195.18). This biopsy contains epidermis and a small amount of dermis, so it is appropriate for pathology in those layers, such as actinic keratosis, verruca, benign nevi, trichoepithelioma, or trichofolliculoma. A full-thickness skin biopsy (punch or excisional) is used for pathology in the deep dermis (pilomatricoma) or when entire architecture

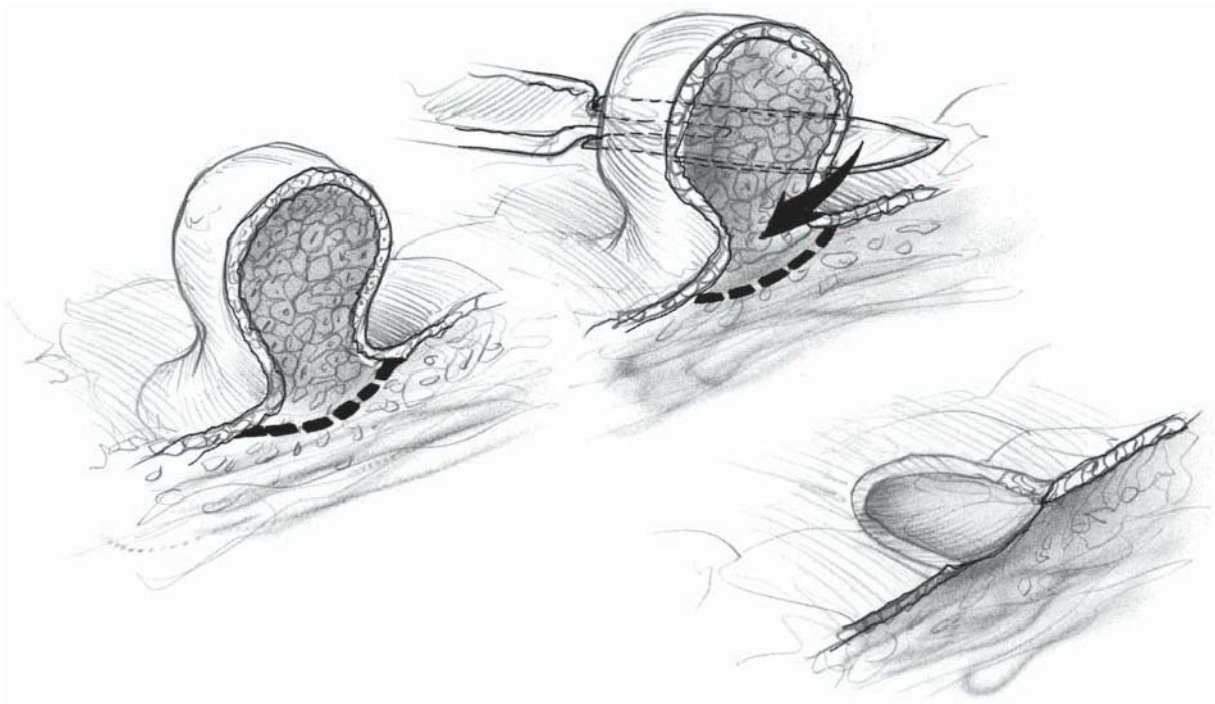

Figure 195.18 Shave biopsy.

Figure 195.19 Punches (3 and 4 mm).

is required for accurate diagnosis (Spitz nevus). Punch biopsies are performed using a 2- to 8-mm circular sharp blade on a handle (Fig. 195.19). It is pressed firmly against the skin and twisted back and forth to penetrate the full thickness of the skin (Fig. 195.20). These are used to diagnose inflammatory conditions or small tumors. For larger lesions, an excisional biopsy is performed. This is used if carcinoma is suspected or the pathologic process involves the fatty layer.

THERAPEUTIC CONSIDERATIONS: TECHNIQUES AND INSTRUMENTATION

Dermal Curette

The dermal curette is a small instrument with a semisharp round to oval blade of variable size (2 to 10 mm) (Fig. 195.21). This allows the surgeon to distinguish between normal and diseased collagen because the semisharp blade will not normally cut through normal collagen. Dermal curettes also are used to remove superficial epidermal lesions, which may be scraped off the skin's surface (seborrheic keratosis, warts) (Fig. 195.22). The instrument is easy and safe to use, but some experience is needed for the surgeon to distinguish reliably between diseased and normal dermal tissue.

Electrosurgery

In electrosurgery, rapidly oscillating electrical fields destroy tissue thermally and mechanically. A monopolar device (e.g., Hyfrecator) requires no grounding plate and results in superficial tissue destruction; a bipolar device requires a grounding plate and causes deeper tissue destruction. Either can be used for electrodesiccation. For electrosurgery, the needle tip is touched to tissue, destroying a deep sphere of tissue. For electrofulguration, the tip

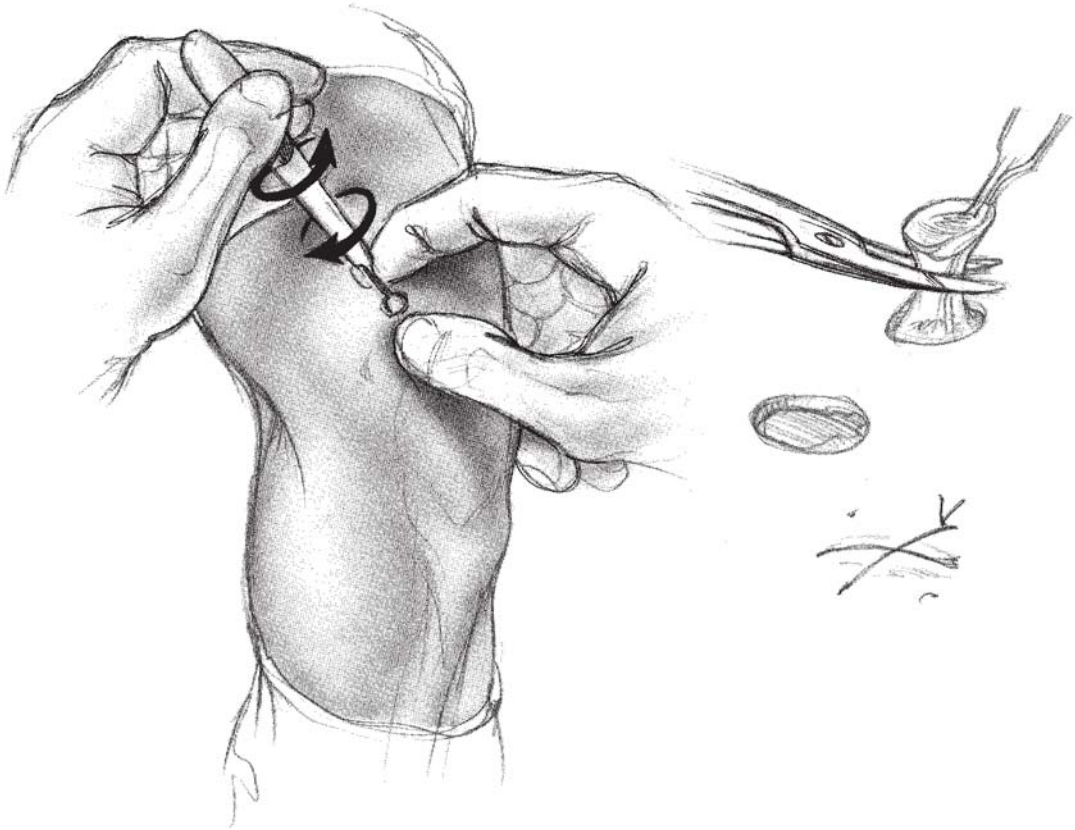

Figure 195.20 Punch biopsy technique.

Figure 195.21 Curettes of various sizes.

is held near the lesion, and a spark jumps from needle tip to tissue, destroying a broad superficial arc of tissue. Figure 195.23 shows electrofulguration with curettage to remove a xanthelasma. Electrosurgery is fast with minimal bleeding, but healing by second intent takes 2 to 3 weeks, there is no tissue for histologic examination, and there can be excessive scarring from thermal damage. Electrosurgery is often used with a dermal curette to define lesion margin or to remove tissue as it is destroyed. Complications include combustion of nondry alcohol-treated skin and interruption of certain cardiac pacemakers.

Cryotherapy

In cryotherapy, a cryogen (usually liquid nitrogen) destroys tissue. Freezing causes formation of extracellular and intracellular ice crystals, resulting in cell membrane damage. Most cell damage occurs during thaw, when electrolyte concentrations become abnormal. Rapid freezing followed by slow thawing is most lethal to cells, with melanocytes being the most susceptible to injury. Tissue destruction is determined by the volume of cryogen applied, the duration of exposure, and the technique used.

A commonly used cryogen is liquid nitrogen, which is the coldest (−196° C) and most versatile agent. Common techniques of application include the cotton-tipped applicator, which is the easiest to learn but evaporates rapidly, necessitating frequent redipping. Spray can also be applied quickly to several lesions but requires skill to direct the cryogen to the specific lesion.

Intralesional Corticosteroid Therapy

Corticosteroid therapy, topical or intralesional, is used to treat inflammatory conditions. Intralesional steroids offer a more concentrated and sustained effect than topical steroids but have more side effects, such as atrophy (usually reversible in 12 months or more) or hypopigmentation (in darker-pigmented skin). Significant systemic absorption can occur when more than 20 mg are injected in a single session or at frequent intervals (Table 195.5).

Intralesional steroids are often used to soften or reduce the size of keloids or hypertrophic scars (10 to 40 mg/mL), repeated every 2 to 3 weeks to minimize systemic toxicity. Intralesional steroid injections also are used after laser or scalpel excision to prevent or reduce recurrence of keloid formation. Intralesional steroids are also used for acne cysts and inflamed epidermal cysts (2.5 to 5.0 mg/mL).

Chemical Peeling

Chemical peeling (chemexfoliation) improves skin quality and texture by applying exfoliants. This causes a variable depth of epidermal and dermal injury that, on healing, has thicker dermal collagen and, in some cases, increased dermal glycosaminoglycans and restoration of elastic fibers in actinically damaged skin. Various peeling agents and

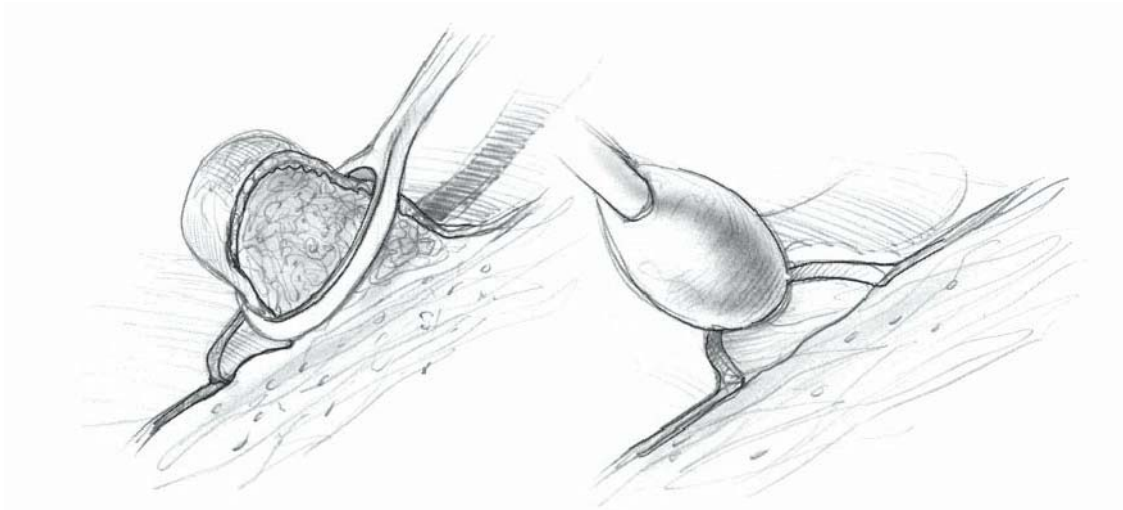

Figure 195.22 Curettage of a seborrheic keratosis.

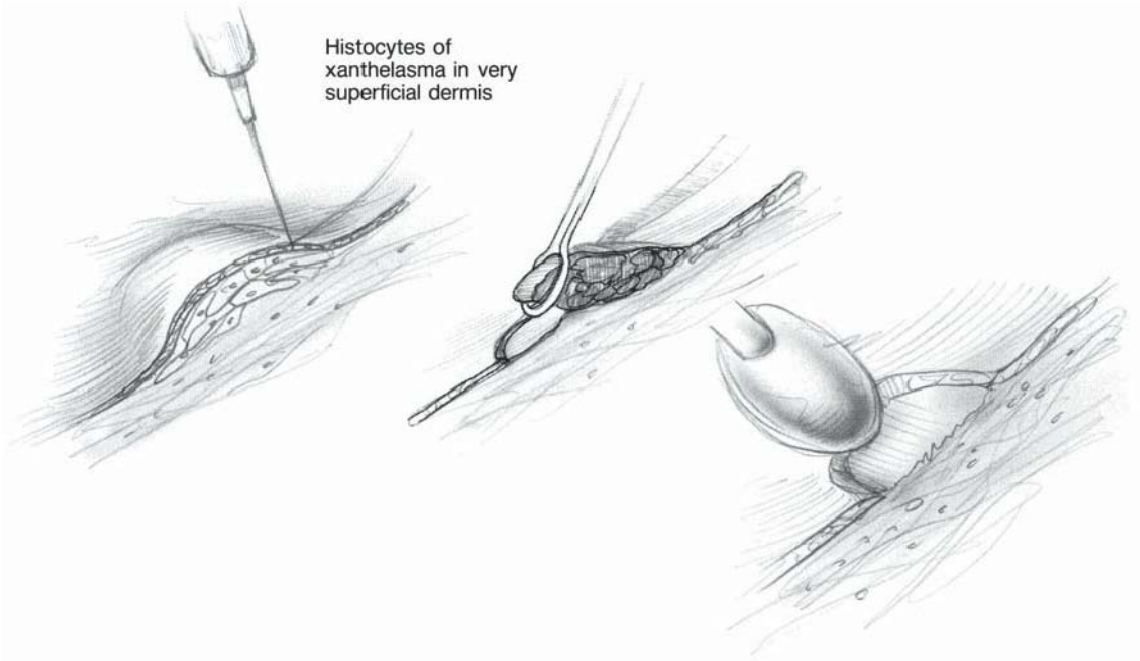

Figure 195.23 Electrofulguration and curettage of a lesion of xanthelasma.

combinations have been used, including trichloroacetic acid, phenol, resorcinol, salicylic acid, and more recently lactic and glycolic acid, each with different properties and depth of penetration. Phenol has a significant risk profile and the potential for systemic toxicity (Table 195.6).

TABLE 195.5 SIDE EFFECTS OF INTRALESIONAL CORTICOSTEROIDS

Local side effects
Atrophy
Striae, stellate pseudoscars
Telangiectasia, purpura, erythema
Hypopigmentation
Impaired wound healing
Exacerbation of cutaneous infections

Systemic side effects
Cardiovascular effects: hypertension
Central nervous system effects: mood alterations, psychosis, pseudotumor cerebri
Endocrine effects: hypothalamic–pituitary–adrenal axis suppression, hirsutism, menstrual irregularities, truncal obesity, moon facies, buffalo hump
Gastrointestinal effects: peptic ulcer, pancreatitis
Hepatic effects: diabetes mellitus
Hematologic effects: lymphopenia, monocytopenia, neutrophilia
Immunologic effects: opportunistic infections
Musculoskeletal effects: osteoporosis, aseptic necrosis of femoral or humeral heads, myopathy
Ophthalmic effects: glaucoma, cataracts (posterior subcapsular)
Renal effects: sodium and fluid retention, hypokalemic alkalosis

Modified from Bondi E, ed. *Dermatology: diagnosis and therapy.* Norwalk, CT: Appleton & Lange, 1991:346, with permission.

Dermabrasion

Dermabrasion is an abrading procedure performed on skin to remove superficial lesions. Initially used to treat acne scars, more recently it has been applied to many cutaneous lesions (Table 195.7). Dermabrasion is performed with a motor-driven instrument with an abrading piece at the end. The abraders (commonly wire brush or diamond fraise) come in various sizes, shapes, and degrees of coarseness.

Competent dermabrasion requires a high level of skill. One must control precisely the depth of the abrasion because prominent scarring occurs if abrasion penetrates reticular dermis. Dermabrasion has similar complications to chemical peeling (Table 195.6). Dermabrasion results can be more predictable than chemical peeling because the extent of wounding can be more precisely controlled.

Laser Surgery

The properties of lasers that make them useful in treating facial lesions (Table 195.8) are precise margination, good

control of destruction depth, good hemostasis, decreased postoperative pain, and target specificity (23). Lasers emit coherent light at specific wavelengths peculiar to the lasing material. This light energy is selectively absorbed by specific skin structures (chromophores) and converted into thermal energy, damaging the tissues. Thermal damage to surrounding tissues can be further reduced by pulsing the laser emission (selective photothermolysis).

Hemostatic Agents

Hemostatic agents are used to control bleeding from removal of superficial cutaneous lesions, which usually results in capillary or venous bleeding.

Monsel solution (ferric subsulfate) is a protein coagulant that is very effective but carries the slight risk of permanent discoloration from iron pigment deposition. Aluminum chloride (20%) is the most commonly used hemostatic agent. It is a colorless but less effective when compared to Monsel solution. Silver nitrate comes conveniently in a stick form or solution but is less effective than Monsel solution or aluminum chloride and can stain skin. It is useful in treating granulation tissue.

All chemical cauterants must be applied to a dry field so there is contact between the bleeding dermal bed and the coagulant. These agents sting when used without local anesthetic.

TREATMENT OF SPECIFIC LESIONS

Seborrheic Keratosis

Seborrheic keratosis lesions are removed by dermal curette or by tangential excision with a scalpel, literally scraped off the skin's surface. If there are numerous lesions, cryotherapy or CO_2 laser can be used. Dermatosis papulosa nigra is treated with light electrodesiccation using fine-tipped cautery needles, then curettage.

Actinic Keratosis

Actinic keratosis lesions usually are treated with cryotherapy. Multiple lesions may require several sessions or alternative therapies, including dermabrasion, chemical peeling, topical 5-fluorouracil (Efudex, Fluoroplex), or topical imiquimod. 5-Fluorouracil comes in concentrations of 1% to 5% and is applied to the face twice daily for 3 weeks. A brisk inflammatory response develops in affected areas. Healing occurs over 6 to 8 weeks and is accelerated by the use of topical corticosteroids. Results are excellent but not permanent, with retreatment often necessary in 2 to 3 years. Imiquimod 5% cream was approved in 2004 for the treatment of actinic keratosis of the face or scalp. Whether administered as monotherapy or adjunctive therapy, topical therapies provide the opportunity to effectively manage actinic keratosis and will likely emerge as an important tool for health care providers (24).

Cutaneous Horns

Cutaneous horns are completely removed (shave or punch technique) so the base can be examined histologically.

TABLE 195.8 LASERS USED IN THE MANAGEMENT OF FACIAL SKIN LESIONS

Laser	Wavelength	Indications
Argon (continuous)	488, 514 (blue–green)	Telangiectasias, thick PWS in adults, lentigines, and ephelides
Argon-pumped tunable dye (continuous)	504–690 (green–yellow–red)	Telangiectasias, thick PWS in adults, lentigines, and ephelides
Flashlamp-pumped dye (short-pulsed)	510 (green)	Lentigines and ephelides
Copper vapor/bromide (quasicontinuous)	511 (green)	Lentigines and ephelides
Krypton (continuous)	521, 531 (green)	Lentigines and ephelides
KTP (quasicontinuous)	531 (green)	Telangiectasias, thick PWS in adults, lentigines, and ephelides
Frequency-doubled Q-switched Nd:YAG (pulsed)	532 (green)	Lentigines and ephelides
Krypton (continuous)	568 (yellow)	Telangiectasias, thick PWS in adults
Copper vapor/bromide (quasicontinuous)	578 (yellow)	Telangiectasias, thick PWS in adults
Flashlamp-pumped dye (long-pulsed)	585 (yellow)	Flat PWS in children, telangiectasias, hypertrophic scars
Q-switched ruby (pulsed)	694 (red)	Lentigines, ephelides, blue nevus, nevus of Ota
Q-switched alexandrite (pulsed)	755 (near infrared)	Lentigines, ephelides, blue nevus, nevus of Ota
Q-Switched Nd: YAG (pulsed)	1,064 (infrared)	Blue nevus, nevus of Ota
Carbon dioxide (continuous, pulsed, super/ultra-pulsed)	1,060 (infrared)	Rhinophyma, trichoepithelioma, syringoma, angiofibroma, keloids, xanthelasma, scars, and rhytides

PWS, port-wine stain.

Usually an actinic keratosis is found, so it is reasonable to curette and electrodesiccate the base lightly after lesion removal. If a squamous cell or basal cell carcinoma is confirmed by histologic examination, a wider excision is performed.

Epidermal Cysts

Small inflamed cysts occur with acne vulgaris and are treated with intralesional steroids in concentrations of 2 to 5 mg/mL. This results in complete resolution in 3 to 5 days, with a low incidence of recurrence. The injection may cause temporary dermal atrophy, which resolves in 6 to 12 months.

Infected cysts are generally large and of longer duration than small acne-associated cysts. They are tender with surrounding erythema. These are best treated with systemic antibiotics, especially those with additional antiinflammatory effects such as tetracycline and erythromycin. For tense and severely inflamed lesions, incision, drainage, culture, and sensitivity determination should be performed, and the treated lesions should be packed with iodoform gauze. Antibiotics against *Staphylococcus aureus* are empirically started. Surgical therapy is deferred for 4 to 6 weeks after infection because infection thins the cyst wall and dermal collagen, making the procedure difficult and increasing the chances of infection spreading. Intralesional steroids should not be used on infected cysts.

The treatment of noninfected, noninflamed cysts is surgical, with complete cyst wall removal (to prevent recurrence). Freely mobile cysts have little connection with the overlying epidermis and are easily removed. Injection of local anesthetics between the cyst wall and surrounding tissues (hydrodissection) facilitates surgical removal.

If the cyst is firmly adherent to the surrounding tissues, the entire cyst and surrounding fibrous tissue are excised. The use of a punch biopsy instead of an ellipse may provide an opening large enough to remove the cyst with excellent cosmetic results. Epidermal cysts that are freely or partially mobile may be removed through incisions at distant sites where cosmetic factors are overriding (e.g., a mucosal approach to remove a lip cyst or an incision in the hairline to remove a nearby forehead cyst).

Complications include infection, bleeding, and dehiscence and are usually a result of poor technique. If the cyst wall ruptures with spillage of keratinous material, the area is irrigated with normal saline and all recognizable

keratinous debris is removed. Necrosis of overlying skin once a cyst is removed usually occurs when a large cyst has been removed, resulting in large dead space with overlying epidermis. To avoid necrosis, all underlying dead space is removed and tension at the skin edges is minimized. Any redundant skin that may occur in cyst surgery is excised.

Milia

A milia is treated by incising its roof and extracting its keratinous core with a milia comedo extractor. No local anesthetic is required. This technique also may be used for large closed comedones. Smaller closed comedones and open comedones (blackheads) are treated with topical retinoic acid (Retin-A).

Trichofolliculomas

Trichofolliculomas are removed by shaving, punch excision with suturing, or vaporization with a CO_2 laser.

Trichoepitheliomas

Solitary trichoepitheliomas are removed the same way as trichofolliculomas. However, distinction of basal cell carcinoma and solitary trichoepithelioma is difficult both clinically and pathologically. Multiple trichoepitheliomas are removed with dermabrasion and CO_2 laser with excellent results.

Pilomatricomas

Pilomatricomas, deep-seated nodules, require surgical excision in most cases.

Trichilemmomas

Solitary lesions of trichilemmoma are treated as trichofolliculomas. Multiple lesions can be treated with dermabrasion.

Nevus Sebaceus

A nevus sebaceus lesion is sometimes completely excised because it has malignant potential; however, its risk for malignancy is low. It also may be followed for changes of malignancy and treated at a later date if necessary.

Sebaceous Hyperplasia

Sebaceous hyperplasia lesions are treated with cryotherapy or light electrodesiccation with fine-tipped cautery needles.

Rhinophyma

Rhinophyma is treated with electrosurgery, dermabrasion, and argon or CO_2 laser. Excessive sebaceous tissue is excised and the nose is sculpted to its predisease shape. Dermabrasion and CO_2 laser allow the surgeon to sculpt with control and precision, the latter maintaining a relatively bloodless field. Regardless of technique, results are usually excellent. Removing tissue below the pilosebaceous apparatus results in an unattractive, unnaturally smooth, poreless scar.

Hidrocystoma

The hidrocystoma cyst is surgically excised if necessary for cosmetic reasons. Simple incision and drainage result in recurrence.

Syringoma

Syringomas usually present as multiple lesions; therefore, surgical excision is usually not feasible. Dermabrasion and superficial CO_2 laser offer fair results on those selected lesions that are more cosmetically concerning to the patient. Electrodesiccation is sometimes sufficient.

Hemangiomas

Most capillary hemangiomas resolve spontaneously, so treatment is usually not necessary. Exceptions are hemangiomas that ulcerate, encroach on a vital structure (nose, eyes, mouth), or are frequently traumatized (buttock, foot). For these, medical therapy (prednisone and interferon alfa) or intralesional corticosteroids are used. A nevus flammeus (port-wine stain) is treated with tunable dye lasers or, more recently, copper vapor, krypton, or flashlamp-pumped pulsed-dye lasers (Table 195.8). Complications are uncommon with these techniques, with occasional hypopigmentation or skin texture alterations. Scarring and tissue induration are rare. Lesions in dark-skinned patients lighten less than others because epidermal melanin causes some absorption of the laser light.

Pyogenic Granuloma

Pyogenic granulomas are treated aggressively because recurrence is common if excision is incomplete. Shave removal with electrosurgery of the base is simple and effective, as is elliptical excision. Ablation with a CO_2 laser, argon laser, dye laser, or copper vapor laser is also effective.

Telangiectasias

Telangiectasias can be treated simply with electrodesiccation using fine cautery needles (epilating needles). The lowest possible setting on a Hyfrecator or Bovie is used to avoid scarring. Telangiectasias also can be treated with laser therapy (argon, argon-pumped tunable dye, copper vapor, krypton, frequency-doubled Nd:YAG, or flashlamp-pumped pulsed dye). Sclerotherapy (injection of sclerosing agent into the telangiectasia) can be used, but there is the potential of introducing

some sclerosant into the cavernous sinus or deep venous drainage of the head and neck, causing potentially grave complications (e.g., blindness, cavernous sinus thrombosis).

Spider Angiomas

Spider angiomas are treated similarly to telangiectasias. In electrosurgery, the needle is placed into the central punctum of the spider angioma. Lesions can recur, so additional treatment may be needed.

Venous Lakes

Small lesions of venous lakes are treated by excision or electrodesiccation. Larger lesions are treated with laser therapy (argon, dye, or copper vapor).

Skin Tags

Skin tags can be snipped off at the base with a sharp curved iris scissors. Local anesthetic is generally not required. Electrodesiccation also can be used.

Fibrous Papule

For a fibrous papule, simple shave excision produces an acceptable cosmetic result and is preferable to superficial destruction methods (CO_2 laser, electrosurgery), which do not permit histologic examination.

Adenoma Sebaceus

Adenoma sebaceus lesions are treated with dermabrasion, CO_2 laser, or argon laser. The argon produces excellent cosmetic results, particularly in patients who have lightly pigmented skin.

Hypertrophic Scars and Keloids

Hypertrophic scars and keloids are managed with intralesional steroids; dermabrasion; pressure; or, most recently, silicone gel matrix. Several treatment strategies often are combined in hopes of better treatment outcomes. Many hypertrophic scars flatten over time. However, long-term results of all treatment options for keloids are poor. Results in the literature are difficult to interpret because most lack long-term follow-up (at least 2 years) and histopathologic criteria to confirm that the lesions are keloids and not hypertrophic scars.

Neurofibromas

Neurofibromas can be excised, CO_2 vaporized, shaved, or removed with electrosurgical cutting current to the base. If the entire lesion is not removed, however, it will regrow slowly. Multiple facial lesions can be dermabraded or excised by CO_2 laser.

Lipomas

Small lipomas can be removed through a small stab incision in the overlying skin. Some lipomas extend insidiously beyond their clinical borders and lie deep to fascia or within muscle. These need to be sharply dissected from surrounding tissue. Giant lipomas may be removed by liposuction. The liposuction cannula is inserted via a small incision. Some lipomas have multiple fibrous septae, requiring careful scissor dissection. Beware of lipomas on the forehead because they often are located beneath the frontalis muscle (subgaleal lipomas). Attempts at excision are frustrating unless the surgeon knows to look in this deeper plane.

Leiomyomas

Leiomyomas are best treated with simple excision.

Melanocytic Nevi

With melanocytic nevi, we are discussing benign nevi, not congenital or dysplastic nevi. Benign nevi can be intradermal, compound, or junctional and can be partly or completely removed. Except for junctional nevi, most nevi are elevated and can be removed by shave technique. This leaves a recurrence risk from residual nevus cells of 10% to 20%. A small hypopigmented area usually results. When a nevus is recurrent, histopathologic interpretation of these often shows atypical or pleomorphic-appearing cells, which can be difficult to distinguish from melanoma (pseudomelanoma).

Two other problems occurring after a shave excision are a depressed scar or peripheral lipping. Depression occurs if local anesthetic infiltration raises the lesion above the skin surface and is avoided by allowing the anesthetic to diffuse out of the lesion before shaving it off. Lipping results if the nevus is not removed flush with surrounding skin because of variable shear forces during shaving. Hemostasis is achieved with aluminum chloride. Monsel solution can hinder histopathologic interpretation of a recurrent nevus because its ferrous subsulfate can be misconstrued as melanin pigment within dermal macrophages.

The second method of removing nevi is complete excision of the lesion. This is necessary for flat nevi. The incision is placed in relaxed skin tension lines. Spot dermabrasion of the scar after 4 to 6 weeks improves the cosmetic result. Complete excision provides a specimen for histologic examination and minimizes recurrence risk.

Spitz Nevi

Spitz nevi are excised for histopathologic examination. This is important because they can resemble malignant melanoma microscopically and the pathologist relies on architectural features lost in a shave biopsy.

Blue Nevi

Simple blue nevi are removed with shave technique or excision. Larger lesions that look like blue nevi are best excised for complete histopathologic examination. Nevi of Ota have been treated successfully with Q-switched Nd:YAG and ruby lasers.

Lentigines and Ephelides

Lentigines and ephelides respond to similar therapy and are similar pathologic processes. For just a few lesions, cryotherapy is probably the easiest treatment. Laser therapy (ruby, alexandrite, pulsed dye, krypton, copper vapor, or frequency-doubled Nd:YAG) is also successful (Table 195.8). For widespread multiple lesions, chemexfoliation is best. A wide variety of agents has been used: retinoic acid, trichloroacetic acid, and alpha hydroxy (glycolic) acids. Retinoic acid carries the fewest risks and is started at low strength (0.025% cream) to minimize irritant effects.

Molluscum Contagiosum

Small numbers of lesions respond well to curettage, cryotherapy, or daily application of topical imiquimod. In patients who are immunocompromised, lesions may number in the thousands and become thick, verrucous, and refractory to treatment. Most recently, chemical peeling with trichloroacetic acid and retinoic acid has been used successfully.

Verrucae

Common and filiform varieties respond well to cryotherapy and electrodesiccation and curettage, although recurrences are common. Flat warts (usually multiple and superficial) respond well to chemexfoliation with retinoic acid or trichloroacetic acid as well as to cryotherapy or topical imiquimod. Harsh keratolytics (e.g., salicylic acid) and blistering agents should not be used in treating facial verrucae because they may lead to scarring.

HIGHLIGHTS

- A classification scheme helps narrow the diagnostic possibilities.
- Seemingly benign facial lesions may be a sign of serious systemic disease.
- Biopsy is the most valuable laboratory aid for diagnosing skin lesions.
- Cosmetic outcomes are important in treating benign facial lesions.
- The risks of all facial surgery should be described to the patient in detail preoperatively.

Management of Alopecia

196

Raymond J. Konior *Steven Gabel*

Burns, traction, infections, autoimmune disease, neoplasms, radiation exposure, psychological disorders, and chemotherapy all can cause hair loss in humans (Table 196.1). The most common type of hair loss in men and women, however, is androgenetic alopecia (AGA), also known as male pattern baldness (MPB). This form of alopecia affects scalp follicles with a genetic potential to androgen inhibition, resulting in the conversion of susceptible terminal hairs to vellus hairs. The hair follicles most likely to demonstrate AGA are in the frontotemporal and the crown regions of the scalp. Several different surgical options are available for restoring hair growth on a balding scalp. The procedure of choice for any given individual will depend on many factors. These include (a) patient's age, (b) degree of baldness, (c) density within the donor region, (d) hair texture, (e) contrast characteristics of the hair and skin, and (f) patient expectations.

A classification system for MPB is essential for planning and comparing the results of different surgical procedures. The Norwood system, the one most often used for men, organizes MPB into seven categories, ranging from class I (minimal frontotemporal recession) to class VII (a very narrow, horseshoe-shaped band of hair in the temporal and low occipital regions) (1). For women, the Ludwig classification system divides hair loss into three grades, ranging from grade I (minimal hair loss) to grade III (severe, generalized thinning) (2). Table 196.2 lists treatment options for MPB.

MEDICAL TREATMENT OF ANDROGENETIC ALOPECIA

Attempts to medically manage MPB are nothing new. Hippocrates, in about 400 BC, prescribed several concoctions composed of animal and plant products to treat baldness.

Ideally, the medical treatment of AGA should be directed against dihydrotestosterone (DHT), the active agent involved in MPB. Finasteride (Propecia), which has been used for years to manage prostate hypertrophy, was approved by the U.S. Food and Drug Administration (FDA) for the treatment of MPB in 1997. Finasteride is a competitive and specific inhibitor of type II 5a-reductase, an intracellular enzyme that converts the androgen testosterone into DHT. Two distinct 5a-reductase isozymes are found in humans. The type II 5a-reductase isozyme is primarily found in the prostate, seminal vesicles, epididymides, and hair follicles. Finasteride has no affinity for androgen receptors but works by blocking the peripheral conversion of testosterone to DHT. Using the recommended dose of 1 mg/d, finasteride produces statistically significant increased hair counts in men with mild-to-moderate degrees of AGA. Systemic therapy that reduces or interferes with androgen levels enough to stop hair loss has the potential to reduce libido and sexual potency, making this form of treatment unacceptable to some men. Drug-related sexual adverse experiences resulting in discontinuation of therapy have been reported in 1.2% of patients on finasteride versus 0.9% of patients on placebo (3,4). Finasteride is not indicated for woman and children.

Minoxidil (Rogaine) was the first drug approved by the FDA for the medical management of MPB. This drug, which traditionally had been used to treat resistant hypertension, was noted to occasionally produce hypertrichosis as a side effect of oral therapy in adults. Minoxidil functions as a potassium channel opener and vasodilator. Currently, the dosages available are 2% and 5% formulations. In men, the 5% minoxidil solution demonstrates a significant advantage over treatment with the 2% solution (5). The mechanism by which minoxidil works to stimulate hair growth remains unclear. In addition, minoxidil does not have any known effect on the production, excretion, or interactions of human androgens. Most, if not all,

Psychological (trichotillomania, stress)

hair transplant surgeons recommend the use of minoxidil and/or finasteride to the majority of their patients (6).

SURGICAL TREATMENT OF ALOPECIA

Patient Evaluation

During the first consultation, the patient's goal of the procedure needs to be discussed. A thorough physical evaluation will need to be performed and an explanation of the surgical options available. The physician must understand the patient's motivations and expectations regarding hair-restoration surgery. Patients who seem emotionally labile may require a psychiatric assessment to evaluate their true motivations, but most patients requesting hair replacement do not have emotional problems; they simply would prefer not to be bald.

Several factors determine what procedure, if any, is appropriate for restoring an alopecic scalp. It is not uncommon for the patient to expect more than can be accomplished with the donor area available. The major reason for rejecting a patient is an inadequate supply of donor hair relative to the patient's final goals.

The ideal patient is one with enough donor hair to completely fill all current or potential areas of alopecia. The younger the patient, the more conservative the physician must be in estimating the donor hair present and establishing a long-term treatment plan. An accurate assessment of the donor area is required to prevent moving follicles at risk for future alopecia into cosmetically important areas on the scalp, because any future hair loss in those transplanted follicles will result in exposed scars over the scalp. In younger patients whose final hair-loss patterns cannot be determined, the physician should try to delay hair restoration until the physician is secure with the availability of donor hair.

Low-density donor hair may be a contraindication to hair transplantation. Patients with fewer than 40 follicular units/cm^2 tend to be poor candidates for hair transplantation, unless they are willing to accept very thin hair density from the transplantation procedures. Age is not a contraindication to hair transplantation. Older patients generally have well-established patterns of alopecia that allow a more reliable assessment of the donor area.

Hair color, skin color, and hair texture are important factors in surgical hair restoration. A sharp contrast between the hair and the skin may result in an unnatural-appearing hairline. This is especially true if transplantation is performed with grafts that contain more than one follicle unit. The best hair colors for surgical hair restoration in light-skinned patients are white, salt-and-pepper, and blond. Patients with dark skin and dark hair and those with wiry hair generally are good candidates for hair restoration. Naturally curly hair appears thicker than straight hair, thereby enhancing the results of most hair-replacement procedures.

Hairline Design

The most important goal of hair-replacement surgery is to restore aesthetic balance to the face by recreating a natural, age-appropriate frontal hairline and part (7). The surgically restored hair should be easy to maintain and should not require extraordinary hairstyles for camouflage.

The mature male hairline usually demonstrates distinct triangular regions bilaterally at the junction of the frontal and the temporal hair (Fig. 196.1). These frontotemporal triangles are formed by progressive recession of the frontal hairline superiorly and the temporal hairline posteriorly.

A natural frontal hairline is convex, with the central portion positioned slightly inferior to the frontotemporal triangle region. The most anterior portion of the hairline is placed approximately 7 to 10 cm superior to the glabella. The apex of the frontotemporal triangle marks the lateral aspect of a natural hairline. Regardless of the extent of hairline recession, the apex is designed to fall on a vertical line drawn upward from the lateral canthus of the eye. Because the temporal hairline intersects the lateral extent of the frontal hairline, advanced temporal recessions require a more posterior frontal hairline. Any attempt to fill a large frontotemporal triangle as a means of compensating for

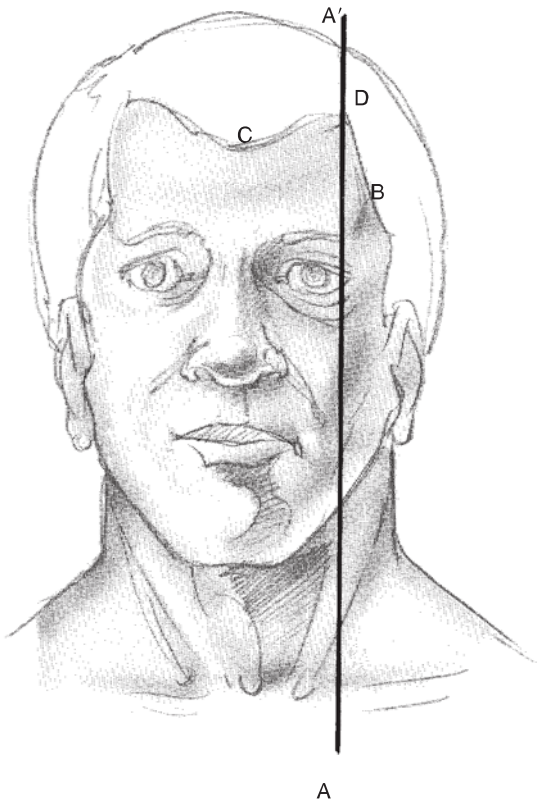

Figure 196.1 The frontotemporal triangle (*BCD*) is defined by the frontal and the temporal hairlines. When planning surgical restoration of the frontal hairline, the apex of the triangle is designed to fall on a vertical line (*AA′*) that intersects the lateral canthus.

advanced temporal recessions will result in an unnatural hairline and part. Modern follicular unit grafting techniques can be used to recreate the temporal hairline in those patients with a low-lying superior temporal fringe.

FEMALE PATTERN HAIR LOSS

In hair restoration, men constitute more than 90% of the patients seeking treatment. As techniques in surgical management continue to improve and public awareness of high patient satisfaction increases, however, there are increasing numbers of women undergoing treatment for hair loss. The approach to female pattern hair loss is much different than MPB, as only 10% of women have an androgenic hair-loss pattern. Therefore, the overwhelming majority of women have hair loss for variety of other reasons, such as hormonal and autoimmune.

The workup involves recognizing the enormous psychological toll hair loss takes on a woman and using appropriate sensitivity when treating women with hair loss. Referral to an endocrinologist is usually part of the workup. Minoxidil 2% solution has been effective in treating female pattern hair loss. Increased dosages of 5% minoxidil have caused unacceptable rates of facial hypertrichosis to occur. Finasteride has not been shown to have benefit in women. Surgical hair restoration remains the only permanent treatment for hair loss in women. The same principles of adequate donor area and advanced transplantation techniques lead to better outcomes (8).

ANESTHESIA

Because most patients require multiple procedures, an adequate comfort level is essential to maintaining motivation for completion of the entire restoration process. Local anesthesia is sufficient for most hair-restoration procedures, but general anesthesia is occasionally necessary for extensive scalp reductions or flap procedures.

A preoperative sedative is commonly given before the injection of local anesthesia. Regional frontal, occipital, and temporal nerve blocks using 1% lidocaine with 1:100,000 epinephrine are performed before performing a wide-field, circumferential scalp block. This technique anesthetizes the entire hair-bearing scalp.

AUTOGRAFT HAIR TRANSPLANTATION

Okuda (9), a Japanese dermatologist, is generally regarded as the first to describe the successful use of full-thickness hair-bearing autografts for correcting alopecia of the scalp, eyebrow, and mustache areas. Hair transplantation using punch grafts was introduced in the United States in 1959 by Orentreich (10). He coined the term *donor dominance* to describe the fact that autografts maintain characteristics of the donor tissue when transplanted into other regions of the body. Patients followed for more than 30 years continue to demonstrate persistent hair growth following punch-graft hair transplantation (11).

Donor Hair Removal: Elliptical Strip Method

The donor site is that portion of the scalp that contains permanent hair dense enough to permit the harvesting of graft material. This area is usually found on the sides and the back of the head and is limited anteriorly by a vertical line through the external auditory canal. The superior border of the safe donor area in the midoccipital region is generally located beneath a horizontal line that intersects the superior attachment of the auricles to the scalp.

In the past, a multiblade knife was used to harvest the donor hair by simultaneously removing several parallel strips of scalp from the donor region (12). The space between the scalpel blades on this device was adjusted to allow the harvesting of different strip widths. Most often, the donor strips measured 1.5 to 3.0 mm in width; the exact dimensions depended on what size grafts the surgeon required for the recipient site. Because of the increased risk of transection and ultimate follicular loss with the multibladed knife, the preferred method for donor hair removal is with a single 1.0- to 1.5-cm-wide elliptical strip. The width of the strip is determined by several factors, including hair density, hair texture, scalp laxity, and scarring from

previous procedures. Using a single scalpel blade to incise the scalp, the donor tissue is obtained with particular care in ensuring the blade is parallel to the angle of follicular growth, thus minimizing damage to the follicles.

Before harvesting grafts, the hair along the donor site is trimmed to about 3 mm. Saline is then infiltrated into the donor site to tense the mobile scalp skin. Donor-site turgidity minimizes the soft tissue distortion that results from pressure generated by the scalpel as it cuts the scalp. Failure to tense the scalp predisposes to irregularly shaped strips and follicular transection. The scalpel blades must parallel the hair follicles to produce an excellent-quality strip. Strip margins are routinely examined during harvesting for evidence of tissue distortion or follicle damage. Poor strip quality may require additional saline infiltration into the surrounding tissues or better alignment of the scalpel blades with the existing hair shafts. The donor strips are removed by incising the subfollicular fat just beneath the base of the follicles. The donor site is reapproximated in the subcutaneous level with a 3-0 Monocryl (poliglecaprone 25) suture, and the cutaneous layer is closed with a running 4-0 nylon suture or staples. A tension-free closure is mandatory to prevent follicular necrosis and a wide scar along the donor-site incision line.

The donor-site strips are examined using magnification, and any transected hair shafts are removed from the edges. Excess subcutaneous fat is trimmed, taking care to leave about 2 mm of fat below the matrix zone of the hair follicles. The strips are then placed flat on a sterile, back-lit cutting surface. Individual grafts (1 to 4 hairs/graft) are made by using a scalpel blade to cut the strips parallel to the path of the embedded follicles. Follicular units used in the hairline should be trimmed to create a teardrop-shaped graft. This method allows for improved density and decreased potential for pitting and graft trauma (13). Different sized grafts can be developed by adjusting the width of the cuts being made along the donor strips. Microscopic dissection techniques are preferred to assure the highest quality, most natural-appearing grafts.

Donor-Site Removal: Follicular Unit Extraction Method

Follicular unit extraction (FUE) is a relatively new technique used for removing individual follicular unit grafts from the donor area using small round punches. In 2002, Rassman et al. (14) developed the FOX system (*follicular unit extraction*), which described the use of 1-mm sharp punches to make a circular incision around the follicles, which are then removed from the scalp. In 2006, Harris (15) described the SAFE method, which uses a two-punch system consisting of a sharp punch to score the epidermis, followed by a dull dissecting punch to separate the follicular unit from the subcutaneous tissue. Recently, powered instrumentation has replaced handheld instruments to allow the surgeon a more efficient method to extract a greater number of follicular units in a single session with less transection (16).

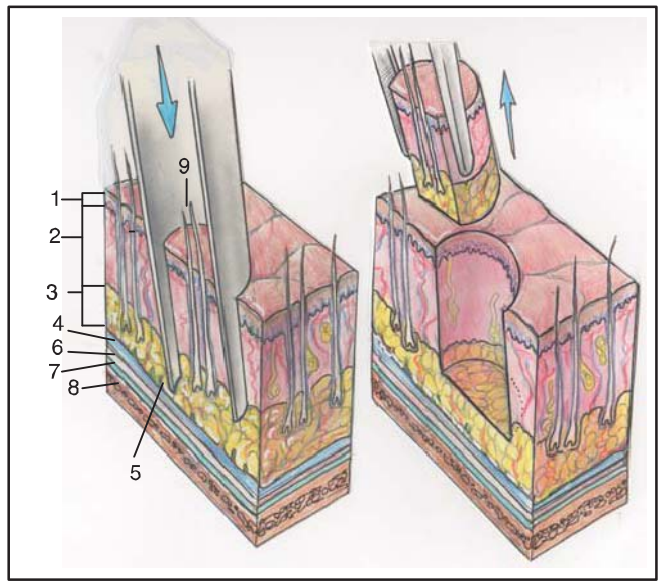

Figure 196.2 FUE is performed using a 1-mm round punch blade to incise the skin down to the subcutaneous tissue. The punch follows the hair(s) in their proper angulation to the base of the follicle. The follicular unit is then gently grasped with an angled forceps and removed. *1*, Epidermis; *2*, dermis; *3*, subcutaneous fat; *4*, galea aponeurotica; *5*, fibrous septum; *6*, subgaleal fascia; *7*, pericranium; *8*, cranium; *9*, 2-hair follicular unit.

The donor-area hair is shaved to 2 to 3 mm in length in order to visualize the curvature to the hair. With the patient in a prone position, local anesthesia with 1% lidocaine with 1:100,000 epinephrine is injected to establish a ring block, and saline is sparingly used intradermally to add turgor to the skin. Typically, a 1-mm round punch blade is used to penetrate the epidermis and dermis around the follicular unit to dissect it from the surrounding tissues. Since this is a relatively "blind" procedure, the angle of the hair must be followed accurately to avoid transecting the graft. Once released, the follicular unit is then gently grasped and removed (Fig. 196.2). This procedure is repeated until the desired number of grafts is obtained. The grafts are then examined under the microscope to assure their integrity and remove any excess skin.

The main advantages of FUE include decreased scarring, allowing people to wear their hair very short; decreased pain; and the ability to harvest hairs from other areas of the body. It is also useful to camouflage wide donor-site scars from prior surgery (17).

Recipient Site

Most alopecic areas can be filled with dense-appearing hair using one to three transplant sessions. Grafts are inserted into the recipient sites made by specially designed blades

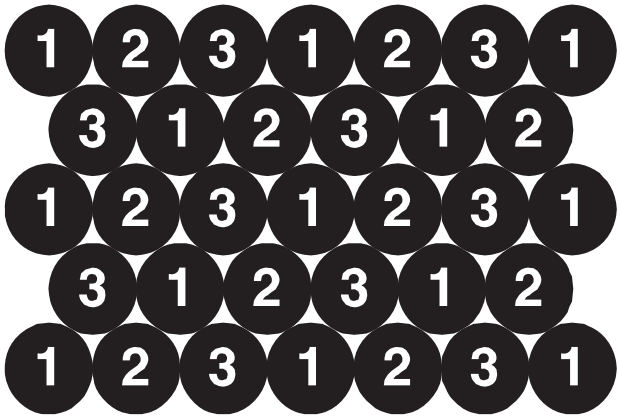

Figure 196.3 Autograft hair transplantation is commonly performed in one to three sessions; a typical grafting sequence is shown. The actual spacing between adjacent grafts during any given session should be sufficient to preserve circulation, but should also maintain a subtle randomness to assure a natural end appearance.

or needles of various sizes. The grafts are spaced evenly apart from each other, taking care to preserve an intact, circumferential bridge of skin between adjacent grafts. This is necessary to maintain adequate circulation around each graft (Fig. 196.3). To maintain a natural hair-growth pattern, the original hair direction and exit angle from the scalp are followed when cutting the recipient site slits or holes. Consistent angling is required throughout all graft sessions to prevent transecting previously transplanted follicles. The hair along the frontal hairline is directed anteriorly at approximately a 10-to-15-degree angle. As the placement of slits extends laterally toward the temple, the hairline is pointed more inferiorly toward the ear and leaves the scalp at a very flat angle.

Modern hair transplantation techniques favor using one of two methods to achieve both density and refinement within the transplanted hairline regions: (a) the exclusive use of follicular unit grafts (18) and (b) combinations of minigrafts and micrografts (19). A follicular unit is a microscopic cluster of closely united follicles. Each cluster of related follicles maintains a microscopically anatomic separation from adjacent follicle unit clusters. A follicle unit usually contains one to four hairs. Follicular unit transplantation requires the use of an operating microscope for optimal graft preparation. The frontal hairline is composed of single hair follicular units, with two to four hair follicular units placed more posteriorly. Microscopic assistance is not used with minigraft and micrograft techniques. Minigrafts contain three to eight hairs, whereas micrografts have only one or two hairs. Micrografts are commonly used to refine the outer perimeter of the transplanted recipient site, especially along the anterior aspect of the frontal hairline. Micrografts soften the transition zone between the bald forehead skin and the transplanted frontal hairline (20). Minigrafts, because of their larger size, are used to create higher density hair, more posteriorly within the recipient site.

Transplantation of the crown requires re-creation of a natural whorl. The center of the whorl usually begins in the middle of the crown's lower quadrant adjacent to the part side. The grafts are angled to mimic a natural whorl, where hair radiates around the predetermined central point.

It is recommended that at least 6 months pass between subsequent transplant sessions. Hair does not grow for an average of 3 months after a transplant session. Therefore, the surgeon should wait 6 months before planning further transplant sessions to evaluate the hair growth from the previous sessions. The surgeon can then examine the quantity and quality of the new hair growth before placing additional grafts. Waiting to see new hair growth also allows the surgeon to precisely and completely fill the spaces left between the previously placed grafts. Crusts form on the grafts soon after surgery and these crusts shed in about 1 to 2 weeks post procedure. The freshly transplanted grafts enter a telogen effluvium phase and lose their preexistent hair over the subsequent 2 to 6 weeks. New hair begins to grow about 10 to 16 weeks after surgery and grows at the normal rate of 1/2 to 1 inch per month. Occasionally, the new hair will appear coarser than the original hair.

Sequelae and Complications

Table 196.3 lists complications of hair-restoration surgery. Most patients experience little discomfort after hair transplantation and require nothing more than acetaminophen with codeine. Severe forehead edema occasionally develops postoperatively; however, this swelling is temporary and may be reduced with postoperative low-dose oral steroids.

Keloidal healing is rare. If any questions regarding a patient's predisposition remain after a thorough preoperative history, a single test graft can be performed at the margin of the fringe. This graft should be observed for 3 to 4 months before scheduling any further transplants. Graft elevation above the surrounding recipient site (cobblestoning) occurs when grafts are not trimmed properly or when there is a size discrepancy between the graft and the recipient opening. Elevated grafts are corrected by shaving the raised epidermal surface parallel to the normal adjacent scalp with a scalpel blade. Cysts can occur when the grafts are placed under the dermis.

TABLE 196.3 COMPLICATIONS—HAIR-RESTORATION SURGERY

Arteriovenous fistula
Hematoma
Infection
Necrosis
Poor hairline design
Scarring
Telogen
Cysts
Poor preoperative planning (donut deformity)

Tissue necrosis at the donor site is rare and usually results from overaggressive harvesting techniques. Wide scars occur when excessive tension is used to close the donor site. Infections following hair transplants occur in less than 1% of patients. Bleeding is unusual and is usually controlled with firm pressure. Arteriovenous fistulae are rare after transplantation and often resolve spontaneously within 3 to 6 months. Direct steroid injection, suture ligation, or complete excision is required for persistent lesions or progressive enlargement.

Poor preoperative planning can result in an unnatural hairline design, or with regard to future hair loss, a disconnect between a patient's transplanted hair and their natural hair.

SCALP REDUCTION

Scalp reductions, seldom performed today, are used to excise bald skin from the crown and central scalp regions. The hair-bearing scalp is undermined and advanced superiorly to cover the excision site. The inherent flexibility of the scalp determines the success or failure of this technique. Patients with extremely flexible scalps may undergo a tremendous excision of bald scalp in a single operation, whereas patients with very tight scalps realize minimal benefit following a standard scalp reduction. This technique is most useful for reducing crown alopecia in patients with Norwood class IV to VI MPB.

Several scalp reduction patterns have been described (21) (Fig. 196.4). The sagittal midline pattern is the easiest to perform, but it creates a central scar over the vertex of the head and a slot that extends into the midoccipital hair-bearing scalp. Although more time consuming, a Y-pattern reduction can be used in place of the sagittal midline pattern to excise crown alopecia without creating a slot-like deformity at the occipital hairline. A variety of other reduction designs, including C, J, S, and lateral crescent-shaped patterns, use laterally placed scars along the fringe of the bald area to reduce crown alopecia without causing unnatural slot formations in the occipital scalp. Lateral patterns, however, are more difficult to perform than midline patterns, and they produce more central scalp hypesthesia.

Most scalp reductions are performed in a prone position using local anesthesia with intravenous sedation. Skin incisions are carried down through the galea aponeurotica, taking care to bevel the scalpel to avoid transecting adjacent hair follicles. A subgaleal dissection is extended inferiorly to the superior attachment of the auricle and to the nuchal ridge. The surgeon can overlap the undermined scalp to estimate a safe excision margin. This technique prevents overexcising the scalp and reduces the potential for excessive incision line tension. The overlapping bald skin is excised with a scalpel, and the scalp is closed in two layers. A secure galea aponeurotica closure is required to minimize incision line tension.

Few complications occur with standard scalp reductions. Occasionally, a deep suture reaction results in suture extrusion and open wounds along the incision line on the scalp. Suture removal and local wound care remedy this situation. Postoperative bleeding, infection, dehiscence, and permanent hair loss are unusual complications. Graft transplantation is usually required to camouflage the mid-scalp and

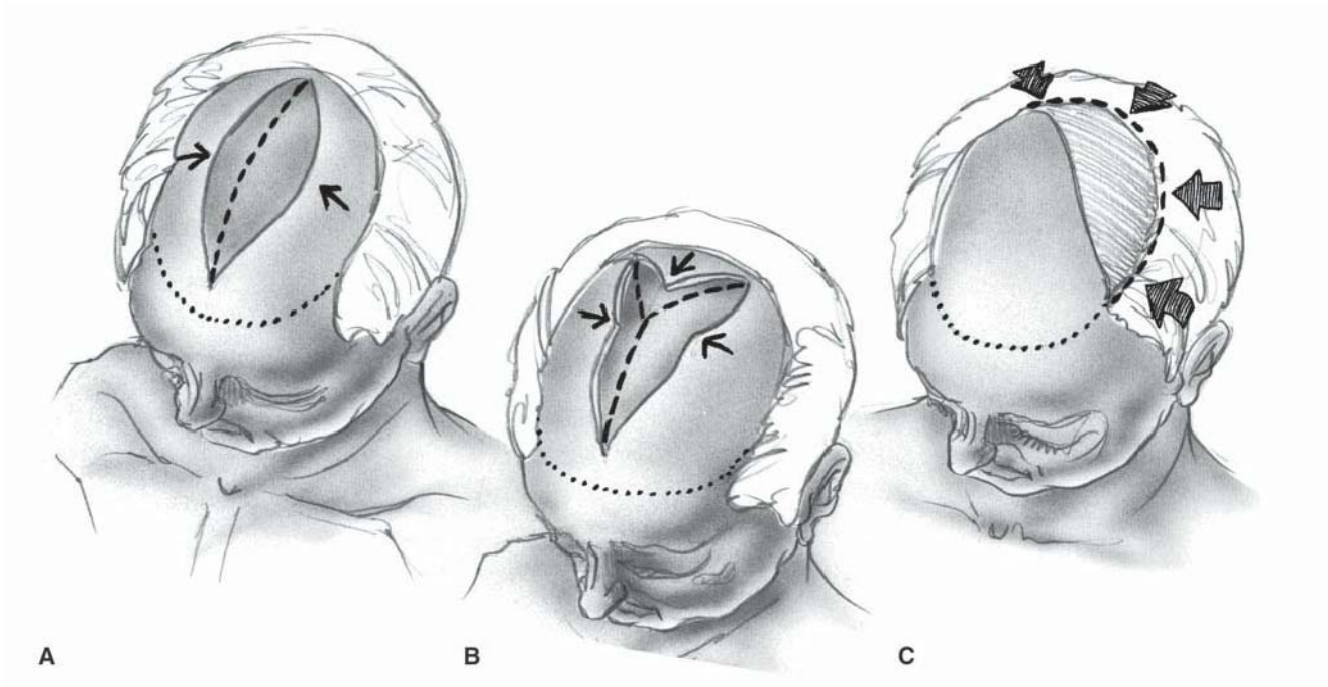

Figure 196.4 Common scalp reduction patterns. **A:** Midline sagittal ellipse. **B:** Y pattern. **C:** Lateral crescent.

crown scars that are produced following a scalp reduction. A poorly executed scalp reduction can produce an unnatural hair direction if the inferiorly directed temporal hairline is pulled too far superiorly to the midline of the scalp.

TISSUE EXPANSION

Scalp tissue expansion redistributes hair follicles in the donor area over a larger surface area on the stretched scalp (22). This technique has been successfully performed in patients with hair loss secondary to trauma, burns, neoplasms, and MPB. Various tissue expanders that allow the surgeon to customize the expansion process for any given area of the scalp are available. This modality is especially useful in patients with MPB who would benefit from a hair-bearing flap or a scalp reduction but are limited by poor scalp flexibility. Tissue expansion enables the surgeon to remove large areas of bald skin without changing the hair color or texture. It is a relatively rapid technique that has few complications when properly performed. The disadvantages include the need for repeated injections to expand the scalp, the pain associated with the injections, and the temporary cosmetic deformity that results with progressive tissue expansion.

Tissue expansion can be used to provide a relatively rapid restoration of hair-bearing skin over the crown and mid-scalp regions in patients with Norwood class IV to VI MPB and poor scalp flexibility. Scalp expanders are designed to expand the entire temporoparietal and occipital donor regions. This technique does not provide hair coverage in the frontal region, however. In patients with coexistent frontal baldness, standard transplant techniques or a modified transposition flap are used after the expansion procedure is completed.

The expanders are placed through incisions along the temporoparietal and occipital fringe (Fig. 196.5). The hair-bearing scalp is mobilized inferiorly to the superior attachment of the auricle and to the nuchal ridge. Remote injection ports are used to prevent accidental puncture of the tissue expander during the inflation process. The expanders are placed flat against the skull, and the injection ports are placed in a separate pocket under the alopecic mid-scalp region. About 30 mL of sterile saline is

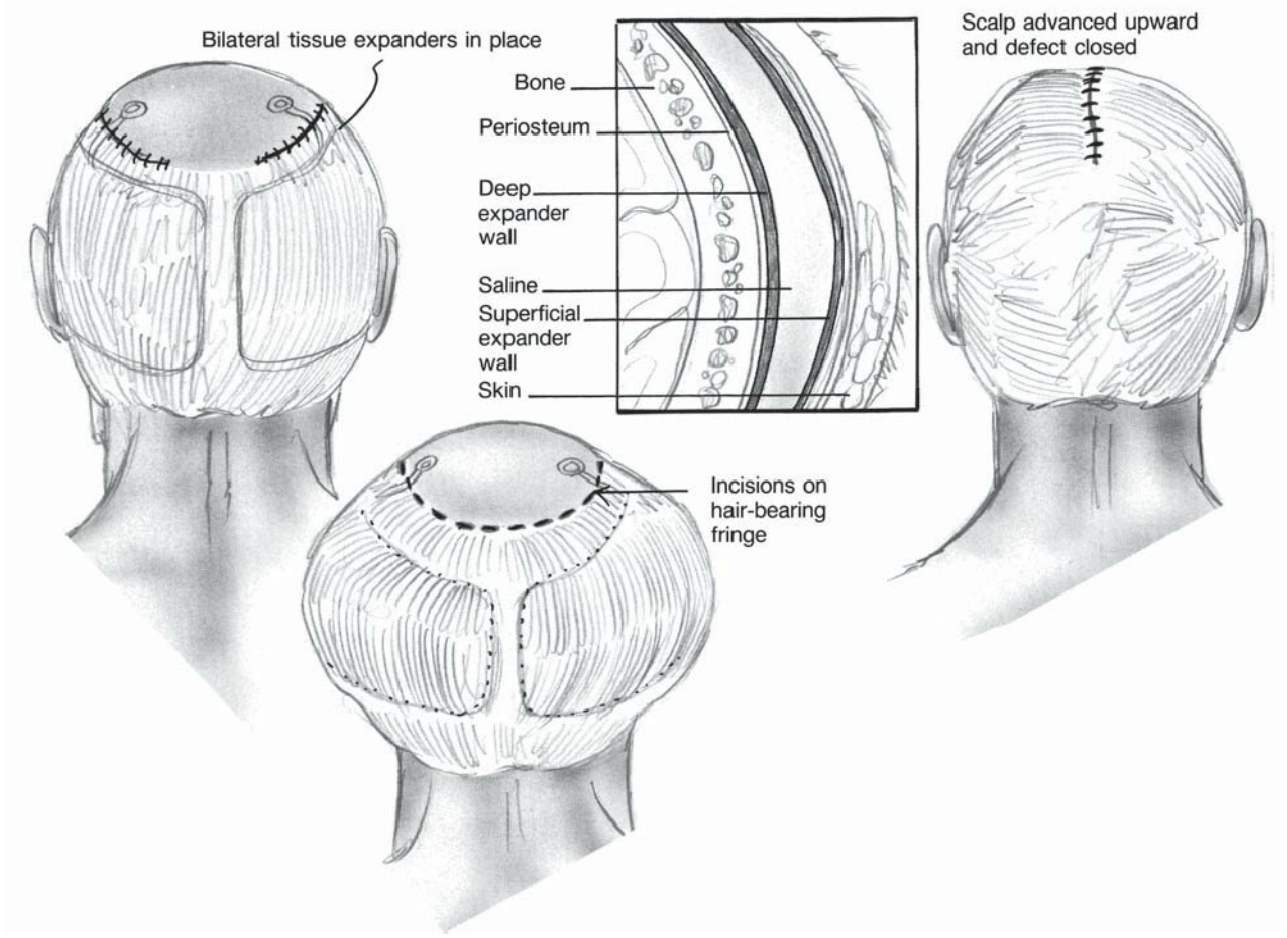

Figure 196.5 Tissue expansion for treating crown and mid-scalp baldness. Tissue expanders are placed bilaterally through incisions (*dashed lines*) along the balding fringe **(left)**. After the expansion process is complete, incisions are made along the hair-bearing fringe, and the bald skin on the crown and mid-scalp is removed **(center)**. The expanded hair-bearing scalp is advanced upward to close the defect **(right)**.

injected into the expanders immediately after skin closure to eliminate dead space.

Tissue expansion begins 2 to 3 weeks postoperatively. The expanders are injected two or three times a week, depending on the patient's pain tolerance during the injection process. Each expander is injected with sterile saline using a 25-gauge needle until the pain threshold is just reached. Each filling session requires about 30 to 60 mL of sterile saline. If pain is a problem, the patient can take a mild analgesic before the injection sessions. The expanders are gradually filled to capacity (500 to 800 mL) over 6 to 8 weeks. Expansion is finished when the cumulative tissue gain across the domes of the expanded tissue exceeds the width of the alopecic defect.

Excision of bald scalp begins by partially deflating the expanders. A horseshoe-shaped incision beginning at the apex of the planned frontotemporal triangle is made superior to the hair-bearing fringe. The expanders are removed, and the expanded scalp is moved superiorly. If additional advancement is required, the capsule is incised inferiorly, and additional undermining is performed. The overlapped bald skin is excised from the top of the head, and the hair-bearing flaps are brought together in the midline.

Complications of tissue expansion include infection, hematoma, exposure of the implant, and implant failure. Proper technique and the use of preoperative and postoperative antibiotics minimize the potential for these complications.

JURI FLAP

The Juri flap, rarely if ever performed today, is a pedicled transposition flap based on the superficial temporal artery (STA) for surgical restoration of the frontal hairline (23). A single flap is used for frontal hairline restoration in patients with hair loss limited to the frontal region. In suitable candidates with more advanced balding over the top of the head, two flaps and a scalp reduction can be staged to provide about 12 cm of dense hair in the frontal and mid-scalp regions.

The Juri flap requires four stages for completion. The first stage begins with designing a hairline and the flap (Fig. 196.6). The STA is identified by Doppler ultrasonography about 3 cm

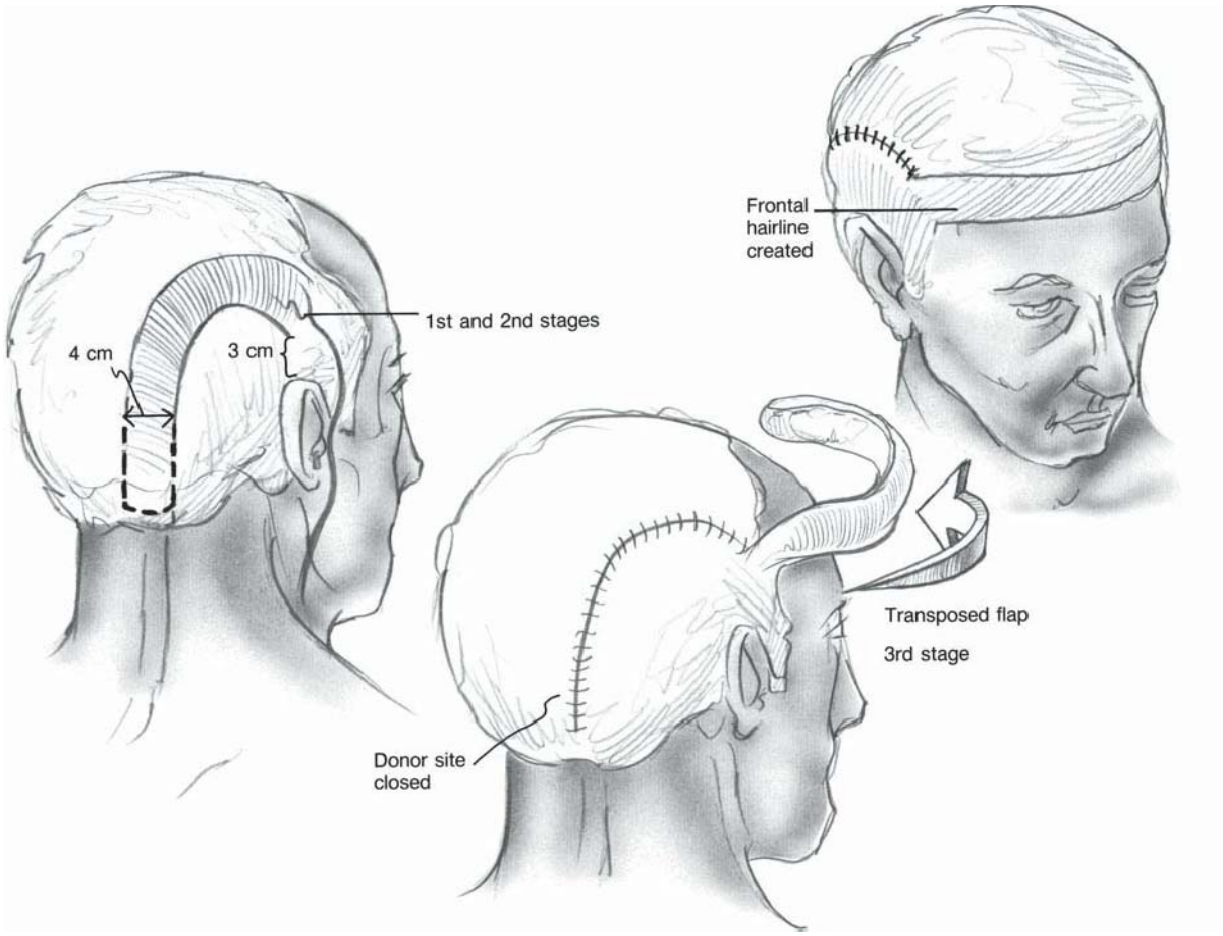

Figure 196.6 The Juri flap. The temporal and parietal portions of the flap are incised during the first stage (*solid lines*). The second stage involves mobilizing the tail of the flap in the occipital region (*dashed lines*) **(left)**. The donor site is closed, and the flap is transposed during the third stage **(center)**. The flap is designed to recreate the frontal hairline **(right)**.

above the root of the helix. The flap is 4 cm wide and has the STA located in the central portion of the base. The base begins posteriorly about 3 cm above the root of the helix and inclines 35 to 45 degrees in an anterior and superior direction. The flap is arched superiorly into the temporal scalp and gently turned posteriorly and inferiorly into the parietal and occipital regions, taking care not to cross the midline or to extend into any areas having the potential for future hair loss. The flap length is determined by measuring the distance from the base of the flap across to the distal end of the frontal hairline. About 4 cm is added to accommodate the "dog ear" that forms when the flap is transposed.

The first two procedures are performed using a local anesthetic. To prevent flap necrosis, epinephrine is never used near the base or the tail of the flap. The first stage consists of incising the proximal three-fourths of the flap through the galea aponeurotica, with attention to maintaining an angle that preserves hair follicles. The flap is not elevated during this stage. One week later, the tail of the flap is incised and elevated to the level of the previous week's incision lines. The occipital vascular plexus is cauterized or ligated and the flap then laid down without entering the region of the prior week's procedure.

The flap is transposed 1 week after the second delay procedure, most often under general anesthesia. The flap is elevated in a subgaleal plane and carefully inspected for adequate circulation at the distal end. A beveled incision is made across the planned anterior hairline, and the scalp is widely undermined in a subgaleal plane superior and inferior to the flap donor site. Homeostasis is checked, and the donor site is closed in layers.

After the donor site is closed, the flap is transposed to lie across the frontal region. A 1-mm strip of epidermis is removed from the frontal edge of the flap with fine forceps and tenotomy scissors. This maneuver allows the surgeon to bury a small strip of dermis along the hairline aspect of the flap below the forehead skin. As hair grows along the deepithelialized strip, it will exit through the overlying forehead skin and incision line, thereby helping to camouflage the frontal scar. The frontal incision line is carefully sutured together. Any overlapping bald skin posterior to the flap is then excised, taking care to avoid tension along the incision line.

Any standing cone deformity that forms at the transposition site is revised 6 weeks after rotating the flap. The flap is cut directly across the dog ear. Limited incisions are made adjacent to this cut along the anterior and posterior margins of the flap. The base of the flap is rotated posteriorly, thus restoring natural hair directionality over the entire temporal scalp. The hairline side of the cut flap is then turned posteriorly to recreate a frontotemporal triangle that is symmetric with the contralateral side. Overlapping bald skin posterior to the flap is excised to accommodate proper flap positioning.

If needed, a second flap is placed 4 cm posterior to the first flap 2 to 3 months after restoration of the frontal hairline. The bald space between the two flaps is excised 2 to 3 months later, resulting in 12 cm of dense hair coverage over the anterior scalp.

One sequela of the Juri flap is the posteriorly oriented frontal hair that results after flap transformation. Severe complications including scalp necrosis and permanent hair loss are more common with flap procedures than with other forms of hair-restoration surgery. These problems are unusual in patients with normal scalp circulation; however, patients with a history of extensive donor graft harvesting over the flap's donor site are especially prone to these complications. Poor hairline design, wide scars, infection, and hematoma are other possible complications of frontal flap hairline restoration (24).

HIGHLIGHTS

- AGA, commonly referred to as MPB, is the most common cause of hair loss in adults.
- Many surgical options are available to manage all but the most severe cases of alopecia.
- Currently, topically applied minoxidil (Rogaine) and oral finasteride (Propecia) are the only medications approved by the FDA for the medical management of hair loss in humans.
- The term *donor dominance* refers to the fact that hair-bearing autografts maintain characteristics of the donor tissue when transplanted into other regions of the body.
- Donor hair is harvested utilizing the elliptical strip method and FUE techniques.
- In the past, standard punch-graft techniques were often criticized for producing unnatural, artificial-appearing hairlines, especially in patients with straight dark hair and light skin color. Technical advances with follicular unit transplants, as well as minigraft and micrograft hair transplants, allow the reconstruction of natural, nonsurgical-appearing frontal hairlines.
- Various scalp reduction techniques are available to reduce crown baldness, offering hope for patients with advanced alopecia who want to attain natural hair restoration over the entire scalp.
- Tissue expansion permits the effective removal and restoration of large alopecic regions in patients with tight, inflexible scalps.

197 Cosmetic Uses of Neurotoxins and Injectable Fillers

Grant S. Gillman

Nonsurgical techniques for facial rejuvenation have become the fastest growing area of many cosmetic practices. The use of botulinum toxin and injectable fillers, either alone or in combination, has proven over time to be an effective, minimally invasive and extremely popular treatment option for facial rhytids. Improved safety profiles, lower costs, negligible downtime and increasing duration of effect have led to the veritable explosion of interest in the nonsurgical treatments of facial aging.

One should begin by understanding the basic difference between the neuromodulators and injectable fillers. Whereas botulinum toxin injections are used to eliminate or soften specific *dynamic* facial lines (i.e., wrinkles produced during animation with active contraction of the facial muscles) by selectively weakening the underlying muscles, the fillers as a group are generally used to help efface facial wrinkles or creases that are apparent even *at rest*. In that sense, botulinum toxin can be thought of as *preventing* selected facial wrinkles from developing or deepening, while the injectable fillers on the other hand are used for the treatment of already *established* rhytids. In many cases, the combination of the two might yield a better result than either product alone.

Distinct facial regions are affected by the aging process in different ways. In general, aging of the upper face results more from repetitive action of smaller muscles with the secondary development of dynamic lines—forehead, glabellar and periorbital (crow's feet). Age-related volume loss (aside from the temporal area) contributes less to the aging of the upper face. Accordingly, the use of neuromodulators such as botulinum toxin plays a greater role in the nonsurgical rejuvenation of the upper face than the dermal fillers. On the other hand, gravitational descent, hollowing and volume loss are the primary determinants of aging changes seen in the midface where the approach to volume restoration and nonsurgical rejuvenation focuses primarily more on the use of fillers than neurotoxins. In the lower face, volume loss in the lips and prejowl sulcus as well as deepening of the nasolabial creases are seen with aging in addition to the development of dynamic perioral lines (vertical upper lip rhytids, marionette lines). In the lower face therefore, selective application of either the fillers or neuromodulators can be useful means of addressing the aging changes seen in this region.

While the risk/benefit ratio for these products is extremely favorable, familiarity with the actions, indications, contraindications, treatment expectations and proper patient selection is vital to maximizing patient satisfaction and minimizing complications. Knowledge of the regional anatomy and proper technique are an equally important part of the foundation upon which successful use of these products is built.

REGIONAL ANATOMY

For the most common cosmetic applications of botulinum toxin, one must be intimately familiar with the relevant muscular anatomy of the forehead, glabella, brow, periorbital and perioral regions, and neck (Fig. 197.1).

Horizontal forehead rhytids are caused by repeated contraction of the frontalis muscle—the sole elevator of the brow. In general, there is a midline separation between the two frontalis muscles, and the vertical contraction of those muscles elevates the brow and scalp leading to the formation of transverse lines in the forehead. The frontalis muscle originates from the galea aponeurotica superiorly and interdigitates with the brow depressors inferiorly. From a clinical perspective, it is important to recognize that isolated treatment of the frontalis muscle—the only brow elevator—leaves the action of the brow depressor muscles unopposed. In some patients, this can result in brow ptosis or a heavy, visor-like feeling to the brow.

Brow elevation by the frontalis muscles is opposed by muscles that function as the brow depressors. These

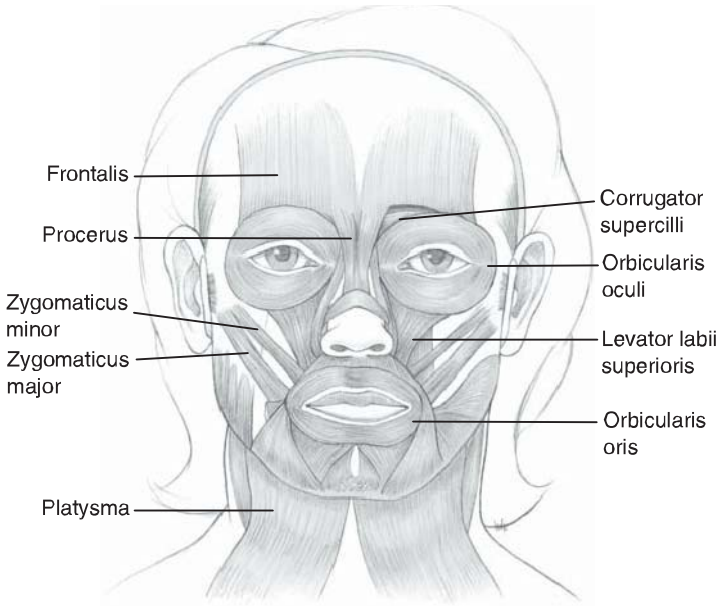

Figure 197.1 Facial musculature.

include the procerus, the corrugator supercilii, the orbicularis oculi and the depressor supercilii (the fibers of the orbicularis below the medial brow).

The procerus muscle originates inferiorly from the lower nasal bones in the midline and runs vertically to blend with the frontalis and insert in the soft tissue between the brows. Contraction of the procerus creates the visible transverse crease at the root of the nose.

The paired corrugator supercilii muscles originate deep to the frontalis and orbicularis muscles near the medial supraorbital ridge where the frontal and nasal bones meet and run superolaterally to insert into the skin and subcutaneous tissue just above the mid-brow. Contraction of the corrugator muscles causes the vertical glabellar lines between the brows (the "frown" lines).

The orbicularis oculi muscle consists of two parts—the orbicular (the outermost portion) and the palpebral, with the latter being divided into preseptal and pretarsal portions. The muscle broadly encircles the orbit, interdigitating with the corrugator muscle medially and superiorly and the frontalis muscle superiorly. Contraction of the orbital portion of the muscle is what produces the lateral orbital rhytids or "crow's feet." Some of the medial fibers of the orbicularis oculi known as the depressor supercilii insert into the skin below the medial eyebrow and also act as medial brow depressors.

The orbicularis oris muscle encircles the mouth and functions both as an oral sphincter and to protrude the lips. Its fibers merge with the depressor anguli oris and the risorius muscles lateral to the oral commissure and the zygomaticus major and minor superiorly. Contraction of the orbicularis oris will result in the fine vertical rhytids that radiate around the upper and lower lips.

The platysma muscle is responsible for horizontal neck creases and vertical bands in the neck. It originates from the fascia overlying the upper chest and clavicle and extends superiorly to insert on the lower mandible and mentum medially and blends with the perioral muscles centrally. More posteriorly and superiorly, the platysma is continuous with the SMAS in the lower two-thirds of the face.

BOTULINUM TOXIN (NEUROTOXINS)

Botulinum toxin injections have become by far the most frequently performed cosmetic procedure over the last decade. In 2008, the use of neurotoxins accounted for almost 25% of all nonsurgical aesthetic procedures (1). Cosmetic applications have expanded, and an increasing number of nonaesthetic applications have been reported as well.

A number of commercially available neuromodulators have been FDA approved for cosmetic applications in the United States. Two of these are formulations of botulinum toxin type A (BoNTA)—onabotulinum toxin A (BoNTA-ONA), which is sold as Botox Cosmetic (Allergan, Inc., Irvine, CA), and abobotulinum toxin A (BoNTA-ABO), which is sold under the trade name Dysport (Medicis Aesthetics, Scottsdale, AZ). Both of these have been approved for the treatment of glabellar lines in addition to their nonaesthetic indications. A third neurotoxin, a formulation of botulinum toxin B, marketed as Myobloc (Solstice Neurosciences, South San Francisco, CA), is FDA approved for nonaesthetic (medical) use and will not be discussed at any length in this chapter. Beyond their FDA-approved medial and aesthetic indications, each of these has been used technically "off-label" in the cosmetic treatment of non-glabellar hyperkinetic facial lines as well.

In addition to differences in the formulation itself, commercial preparations may differ with respect to pH, protein content, purification and manufacturing methods as well as other characteristics (2). It is likely that these differences

account somewhat for the variations in clinical characteristics and performance. As a result, there is no single conversion factor that yields *exact* equivalents of efficacy, safety and diffusion between the various preparations, and BoNTA-ABO units are not interchangeable with BoNTA-ONA units (the two main botulinum toxin preparations used clinically). In general, however, BoNTA-ABO (Dysport) is less active on a per unit basis than BoNTA-ONA (Botox Cosmetic), which means that more units are required to achieve a comparable effect. That said, the literature with respect to dose conversions can be confusing, variable in rigor and validity and not free of commercial bias. More recently published literature suggests that one unit of BoNTA-ONA (Botox Cosmetic) is roughly equivalent to 2 to 4 units of BoNTA-ABO (Dysport) for a ratio of 2:1 to 4:1 (3).

Mechanism of Action

Clostridium botulinum is a gram-positive anaerobic bacteria that produces eight antigenically distinct toxins (A, B, C1, C2, D, E, F, and G), seven of which are neuroparalytics. The neurotoxin produces a temporary chemical denervation by inhibiting the release of acetylcholine from the presynaptic neuron at the motor end plates of voluntary muscle. All seven serotypes share the same mechanism of action, inhibiting acetylcholine release at peripheral nerve endings, but differ with respect to molecular complex size, presence or absence of complexing proteins and specific details in their sequence of action (4).

The flaccid paralysis that follows is temporary in nature. Chemodenervation is followed by a two-stage recovery process. Initially, there is growth and sprouting of new axonal collaterals which establish new connections at the motor end plate. At about 3 months, neural transmission through the original (primary) nerve terminal is reestablished and the collateral axons regress (5). This correlates with clinical recovery of function typically in the range of 3 to 4 months postinjection.

Indications and Contraindications

Botox Cosmetic is currently FDA approved for therapeutic use in cervical dystonia, strabismus, blepharospasm and hyperhidrosis and cosmetically for the temporary improvement in vertical glabellar rhytids caused by the action of the corrugator and procerus muscles. Dysport is FDA approved for therapeutic use in the treatment of cervical dystonia in adults and cosmetically for the temporary improvement in glabellar lines. Although technically "off-label," the clinical use of these BoNTA preparations has expanded widely to include the treatment of many other conditions including other facial hyperkinetic lines, migraine headaches, hyperhidrosis, bruxism, Frey syndrome, muscle tension dysphonia, torticollis and bilateral masseteric hypertrophy to name a few.

The use of any botulinum toxin is contraindicated in individuals with preexisting neuromuscular disorders (e.g., myasthenia gravis, amyotrophic lateral sclerosis, Eaton-Lambert syndrome) and patients with a sensitivity to any other botulinum toxin product, an albumin allergy, or cow's milk protein allergy (in the case of Dysport; as distinct from patients who are lactose intolerant). Use in pregnant women or lactating mothers is not recommended as there is no safety data regarding use in such circumstances.

Cosmetic Applications of Botulinum Toxin

Commercially available Botox Cosmetic is supplied in a crystalline form as 100 unit vials, whereas Dysport is supplied with 300 units per vial. Both products are diluted with sterile, preservative free normal saline. The volume of dilution depends on the preference of the treating physician. Most prefer dilutions that yield concentrations of 2 to 5 units of Botox Cosmetic per 0.1 mL as this product is typically injected in 2 to 5 unit aliquots (per injection site). Dysport is generally diluted to yield concentrations of either 10 units per 0.1 mL or 10 units per 0.05 mL as this product is typically injected in 10-unit aliquots (per injection site).

The volume of dilution (and hence the concentration) can vary with the clinician's preference, but the underlying principle is that high concentration–low volume injections will help minimize unwanted dispersion of the toxin to surrounding tissues. According to the product information, it is recommended that once reconstituted botulinum toxin should be used within 4 hours, although many clinicians have refrigerated any unused toxin for use up to 30 days (6) and found it to still be clinically effective. In one study of timing of onset and duration of effect in the treatment of forehead rhytids, no difference was found between freshly reconstituted Botox Cosmetic as compared to the same product which was either reconstituted and stored in a refrigerator for 2 weeks or reconstituted and stored in a freezer for 2 weeks prior to use (7).

Following injection, the onset of muscle weakness with BoNTA generally occurs between 2 and 5 days. Botulinum toxin type B (Myobloc) has been shown to have a faster rate of onset than BoNTA formulations—often within 24 hours (8). In general, the duration of response to the BoNTA preparations is similar to one another and should last on average 3 to 4 months before full muscle recovery is noted, though comparative studies looking at physician and patient evaluations of improvement and satisfaction suggest that Botox Cosmetic may have a longer duration of effect than Dysport (9,10). Myobloc on the other hand has a shorter duration of action than either formulation of BoNTA, with efficacy lasting only up to 8 weeks (8).

Although there are many potential applications for the use of botulinum toxin, this chapter will review in general terms only the most common uses for improving facial aesthetics—the treatment of glabellar rhytids ("frown lines"), transverse forehead rhytids, lateral periorbital rhytids ("crow's feet"), the adjustment of brow contour and position (the "chemical"

browlift), the treatment of platysmal banding in the neck and vertical upper lip rhytids.

Differences in either injection site specifics or individual adjustments in dose will be apparent from patient to patient and may result from variations in muscle bulk, animation pattern, severity of rhytids, previous results and unique anatomic variations. Keeping detailed treatment records with respect to site, dosage and differences will facilitate reproducibility and improve patient satisfaction. Injection technique is essentially the same regardless of which formulation is used.

Glabellar Rhytids

Glabellar rhytids include the vertical "frown" lines produced by contraction of the corrugator supercilii muscles as well as the transverse crease at the nasion produced by contraction of the procerus. Injection points for glabellar rhytids should target the procerus in the region of the nasion at the intersection of two lines, each of which extends from the medial brow to the opposite medial canthus. Each corrugator muscle is injected medially and laterally into the belly of the muscle above the medial brow roughly in line with the medial canthus and further laterally along the muscle, staying medial to the mid-pupillary line (Fig. 197.2). The latter two injections should always be at or above a transverse line drawn though the mid-eyebrow and above the superior orbital rim to minimize the chance of diffusion into the levator palpebrae of the upper lid which could result in a transient eyelid ptosis (11).

Transverse Forehead Rhytids

As the frontalis muscle is the only elevator of the brow, isolated treatment of horizontal forehead lines must be done with caution. In the patient with heavy glabellar rhytids or a very low brow one should assume that the brow depressors are quite strong and active, in which case isolated treatment of the frontalis muscle may cause or further aggravate brow ptosis. In such cases, concomitant treatment of the brow depressors (corrugators, procerus) should at the very least be discussed with the patient.

Figure 197.2 Typical botulinum toxin injection pattern for glabellar rhytids/corrugator creases.

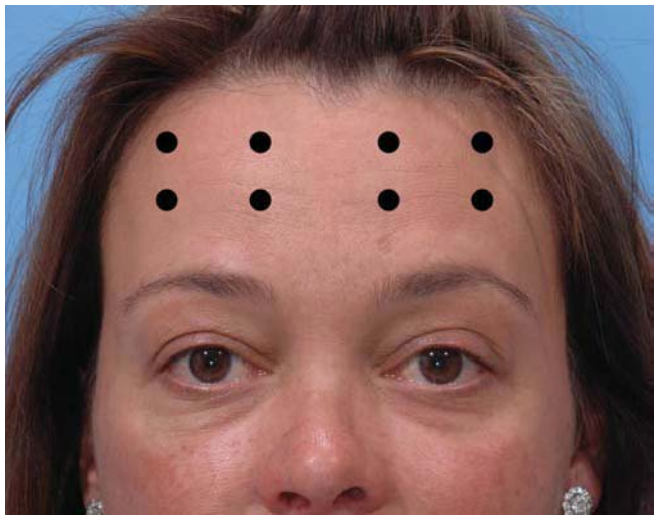

Figure 197.3 Typical grid-like botulinum toxin injection pattern for transverse forehead rhytids.

Effective treatment of the transverse forehead rhytids involves subcutaneous or intramuscular injections into the frontalis muscle, either in a relatively uniform grid-like fashion across the forehead (Fig. 197.3) or at four to five equally spaced sites on a horizontal line between the eyebrows and the hairline. Care is taken to stay a minimum of 1 to 1.5 cm above the brow for all injections to minimize the risk of eyebrow ptosis. Simultaneous treatment of brow depressors, if undertaken, can involve the procerus and/or corrugators and/or the lateral orbicularis oculi above the orbital rim and just below the tail of the brow.

Lateral Periorbital Rhytids

Lateral periorbital rhytids ("crow's feet") result from repeated contraction of the lateral portion of the orbicularis oculi muscles. As this muscle is very thin and superficial, intradermal or immediately subdermal injections are sufficiently deep and will help minimize the bruising that can occur commonly in this area. Injections should also be on an arc at least 1.5 cm lateral to the lateral canthus and 1 cm outside the lateral orbital rim to minimize the chance of any diffusion through the lid into the levator palpebrae superioris which could result in upper eyelid ptosis. Treatment of the crow's feet is best avoided in anyone with a preexisting upper eyelid ptosis, lagophthalmos or upper facial palsy.

Having the patient smile or squint will help identify the specific area or lines in need of treatment. Multiple serial injections are then used, typically two to four, perpendicular to the muscle and just outside the orbital

Figure 197.4 Typical botulinum toxin injection pattern for lateral periorbital rhytids.

rim (Fig. 197.4). The amount injected per site will depend on the distribution of the lines and the activity of the underlying orbicularis oculi.

Adjustment of Brow Position and Contour (The "Chemical Browlift")

At least to some degree, brow position is the result of an equilibrium reached between the action of the brow elevator (the frontalis) and the opposing action of the brow depressors (the corrugator, the procerus, the orbicularis oculi and the depressor supercilii) (12,13). As such, selective weakening of the brow depressors with botulinum toxin, either medially or laterally, may result in a modest (several mm) "pharmacologic" brow lift.

Elevation of the entire brow will require attention to both the medial and the lateral brow depressors. Frequently, elevation of only one end of the brow or the other might be desired in which case it suffices to address those muscles only. For elevation of the medial brow, treatment of the corrugators and procerus as well as the depressor supercilii is required. The latter muscle is treated with an injection of a small dose just below and just lateral to the medial head of the brow, taking care to remain outside the orbital rim to avoid unwanted diffusion into adjacent muscles. Elevation of the lateral brow requires a subdermal injection of the orbicularis oculi muscle just below the eyebrow lateral to the high point of the brow, once again remaining outside the orbital rim. One to three injection sites may be required.

Platysmal Banding

Administration of botulinum toxin to platysmal bands can be a useful adjunct in the treatment of the senescent neck (14). Best results are seen with mild to moderate banding (15), and the changes are most appreciable with dynamic contraction of the platysma than at rest.

Having the patient contract the muscle will best demonstrate the platysmal bands, which are then grasped and injected with botulinum toxin at multiple sites each 1 to 1.5 cm apart, from below the jawline to the lower neck. Typically, each band will receive a total of about 15 units of Botox Cosmetic or 40 to 80 units of Dysport per band. Caution must be exercised to avoid excessive doses and to inject into the muscle but not deep to it. Overly deep injections can increase the risk of dysphagia and/or neck weakness.

Vertical Lip Rhytids

Very low doses of botulinum toxin injected into the orbicularis oris muscle of the upper lip can help efface or soften vertical upper lip lines. This treatment may be an alternative to perioral chemical peels or laser resurfacing and can be used alone or in combination with injectable fillers. In order to avoid problems with oral incompetence the injections are kept very superficial (subdermal), and very small doses are used initially. Nonetheless, professional public speakers and wind instrument musicians may not be ideal candidates for this treatment.

Four evenly spaced injections are given across the upper lip at or immediately above the vermilion border. Starting with lower doses and increasing if necessary is most prudent. In addition to reducing the depth of apparent vertical lip lines, some degree of lip eversion is also frequently noted.

Botulinum Toxin Complications

As noted earlier, the safety profile of neurotoxins when used for cosmetic applications is quite favorable. In fact, the safety, combined with favorable and reproducible outcomes accounts for the popularity of the procedure. Sound knowledge of the regional anatomy, attention to proper doses and technique and the use of high concentration–low volume dilutions all help minimize the incidence of unwanted side effects. Larger volumes can lead to inadvertent and undesirable spread to adjacent nontargeted tissues. Since the effect of any neurotoxin is a temporary one, so too are the complications. There have been no deaths reported or adverse long-term effects from the cosmetic use of neurotoxins (16).

Medications that might potentiate the activity of botulinum toxin include aminoglycosides, cyclosporins, neuromuscular blockers, calcium channel blockers, quinidine, magnesium sulfate and D-penicillamine.

General sequelae of botulinum toxin injections include pain, erythema and bruising at the injection site, headache, flu-like symptoms, malaise and fatigue. Injection pain can be minimized by using small gauge needles as well as slowly inserting the needle and injecting slowly. Aside from

Figure 197.5 Left eyelid ptosis resulting from diffusion of botulinum toxin into levator palpebrae superioris muscle.

injection-related discomfort, erythema and perhaps bruising, the others are much less common. Headaches occur in about 1% of patients, and patients should be informed of this possibility (17).

Site-specific complications should be infrequent if suitable consideration is paid to technical detail. The most significant complication of glabellar or lateral periorbital injections is upper eyelid ptosis (Fig. 197.5). Ptosis results from migration of the injected toxin deep to the orbital septum where it may affect the levator palpebrae superioris of the upper eyelid. Staying outside the orbital rim with all injections (as indicated earlier) should prevent this complication from developing. In addition, one should avoid massaging the area as this may encourage unwanted dispersion of the product. Upper eyelid ptosis can develop up to 1 week after injections and usually resolves within 2 to 6 weeks. Should it develop, ptosis can be treated with alpha-adrenergic ophthalmic drops such as Iopidine 0.5% (Apraclonidine, Alcon Laboratories, Fort Worth, TX) or Mydfrin 2.5% (Phenylephrine 2.5%, Alcon Labs), both of which stimulate Mueller muscle to help elevate the eyelid margin (18). The typical dose is one to two drops three times daily until the ptosis resolves. Injection of the crow's feet can also result in diplopia by affecting the lateral rectus. For this reason, it is important to stay at least 1 cm outside the lateral orbital rim at all times.

Treatment of the frontalis muscle for transverse forehead rhytids can result in brow ptosis, which is best avoided by staying at least 1 to 1.5 cm above the brow. Older patients, those with a low-set brow and those with very active brow depressors are at greatest risk. Should brow ptosis develop, patients can be reassured that the frontalis muscle will return to its baseline activity within 3 to 4 months. Alternatively, brow ptosis can be alleviated, if necessary, by secondary treatment of the brow depressors if this has not already been performed.

Injection of the platysmal bands may also cause unwanted secondary effects. If the injection is too deep it can affect the larynx and hypopharynx, resulting in dysphagia or hoarseness. If the injection is too far lateral weakness of the sternocleidomastoid muscle can occur. Staying superficial and avoiding excessive dosing are critical. Dietary modification (soft foods, liquid diet) and metoclopramide hydrochloride may be necessary for severe dysphagia (18).

Lip weakness or oral incompetence may result from perioral use of botulinum toxin. Prevention is most important and requires use of very low doses initially together with superficial placement.

Resistance to botulinum toxin type A may result from the formation of neutralizing antibodies. This is generally associated with repeated use of high doses (above 300 units) and is relatively uncommon with the lower doses used for cosmetic applications (19). If antibodies to botulinum toxin A develop, the use of botulinum toxin type B may be of benefit (8).

Finally, patient dissatisfaction may result from overtreatment, undertreatment and unmet or unrealistic expectations. Proper patient selection, education and counseling together with consistent procedural skills will help limit the number of unhappy patients.

SOFT TISSUE AUGMENTATION

The use of injectable materials for soft tissue augmentation has a long history dating to Neuber (20) in 1893 when he harvested fat from the arm and injected it into a patient's facial defects. Since that time, many other materials have been developed in the search for a filler substance to correct facial scarring from trauma and acne, static rhytids and malar and lip and melolabial crease augmentation.

In the early part of the 1900s, paraffin injection became popular. This quickly fell out of favor however secondary to repeated granulomatous-type foreign body reactions resulting in paraffinomas. In the 1940 to 1950s, injectable silicone was introduced. Long-term studies with this material however revealed a potential for granulomatous reactions and scarring and so FDA approval was ultimately withdrawn in the 1980s. In the 1970s, Stanford researchers experimented with animal- and human-derived collagen as implantable materials that eventually led to the introduction of bovine collagen (21).

In recent years, research and development in this area has been intense due to the popularity of dermal fillers. Patient demand in this area is high because injectable fillers offer distinct advantages over surgical procedures. The benefits of injectables for soft tissue augmentation include that injections can be performed on an outpatient basis with minimal or no recovery time and they offer immediate results with lower short-term costs than surgical procedures. Additionally, the ease of touch-ups when necessary and consistently improved safety and duration of effect are attractive to patients. Furthermore, certain defects are more easily corrected with contour filling rather than surgical intervention.

However, the *ideal* filler has yet to be found. The ideal filler would be easy to use, biocompatible and without risk of allergic reactions, immunogenic toxicity or carcinogenicity. It would be inexpensive and have an inexhaustible source. The ideal filler material would also be well tolerated and accepted by the host so that long-term correction could be achieved without risk of complication.

In general, most of the currently available materials are made to be injected into the dermis or subdermal. The dermis is the middle layer of the integument composed of viscoelastic tissue lying between the epidermis and the subcutaneous tissue. The predominant cell type in this layer is the fibroblast that secretes the cellular matrix of type I collagen and elastin. Collagen fibers provide tensile strength, while the elastin is responsible for elastic recoil (22). These fibers are embedded in a gel-like ground substance of glycosaminoglycans. The primary polysaccharide of this extracellular matrix is hyaluronic acid (HA), which provides a framework for collagen and elastin to bind and potently binds water maintaining skin turgor. With aging, the concentration of HA in the skin diminishes with a resultant loss of volume, turgor and cellular hydration.

There is no single means of classifying fillers. Currently used dermal fillers can be divided into categories based on the relationship to the donor (xenografts—donor and recipient are different species; autografts—donor and recipient are the same individual; homografts—donor and recipient are same species; and synthetic materials), their duration of effect (temporary vs. permanent) or their chemical makeup (collagens vs. hyaluronic acids vs. biosynthetic polymers). Products available function either as *volumizers* that are relatively neutral and provide bulk (temporarily or permanent) but cause minimal foreign body reaction, or *stimulators* that stimulate tissues by causing a foreign body reaction which then results in new collagen formation.

In general, the deeper the defect the more viscous the filler and the deeper the desired plane of injection. Superficial lines are typically addressed with fillers of smaller particles placed into the upper dermis, whereas fillers of larger particle size (thicker consistency) are injected into the deeper dermis or into the subdermal plane to treat deeper furrows and for larger volume augmentation. Layering techniques, using multiple products, are often used where both volume addition and the effacement of superficial fine lines are desired.

The currently available fillers are approved for the correction of moderate to severe wrinkles and folds and in some cases for the treatment of facial lipoatrophy. The other commonly reported clinical applications such as the correction of soft tissue depressions and volume augmentation (e.g., malar, prejowl sulcus, lips) are off-label uses of these products.

The discussion of dermal fillers that follows is not intended to be exhaustive. There are constantly new products in development that may ultimately prove to be more effective than existing ones, and within little time of any review or publication newer products become available, and others are discontinued. As such, this portion of this chapter is intended to be an overview and should not be regarded as a definitive or comprehensive resource.

Collagen Products

Bovine collagen was the most widely used dermal filler from the time of FDA approval in 1981 until the last decade and has by far the longest track record. Up until the early 21st century, injectable collagen remained the gold standard to which other fillers were compared. As collagen is a major component of the skin's structure, its use as an injectable filler was a logical extension. Owing to widespread development of second- and third-generation dermal and subdermal fillers that are hypoallergenic, safer and longer lasting, distribution of collagen products was halted by the manufacturer in 2010. A brief discussion of collagen is included here for its historical relevance.

Three types of bovine collagen were commercially available. Zyderm I, Zyderm II and Zyplast (Allergan Inc., Irvine, CA) are all derivatives of enzyme-digested bovine collagen—primarily type I—suspended in phosphate buffered saline and lidocaine. During the preparation, antigenicity is reduced by pepsin proteolysis (23). All three of these collagen fillers were made up of 95% type I bovine collagen and 5% type III bovine collagen.

Zyderm I contains 35 mg/mL of collagen and was approved by the FDA in 1981. As the concentration of collagen in Zyderm I was quite low there was significant resorption of this product, and so Zyderm II containing 65 mg/mL of collagen was introduced and approved by the FDA in 1983. It was felt that the higher concentration of collagen translated to longer duration of effect. Zyplast, on the other hand, contains 35 mg/mL of collagen cross-linked with glutaraldehyde in order to make the material less susceptible to enzymatic degradation and resorption, thereby delivering a longer lasting result. All of these products lasted approximately 3 to 5 months—ultimately, a competitive disadvantage.

Zyderm was recommended for superficial mild to moderate wrinkles such as the glabellar creases, periorbital crow's feet and perioral rhytids. The product was injected into the upper dermis. Because of early resorption with this material a slight overcorrection was required. Conversely, Zyplast was injected into the deeper reticular dermis, and since it was more resistant to resorption overcorrection was not needed.

The primary disadvantage of bovine collagen was the risk of a hypersensitivity reaction manifesting as induration, erythema, pruritus and tenderness at the injection site. Skin testing for allergic sensitivity was therefore required prior to definitive use. About 3% to 4% of patients undergoing skin testing developed a hypersensitivity reaction (24,25). Although in the majority of allergic

patients a reaction to skin testing was apparent in the first week, about 20% to 30% demonstrated a delayed reaction for which it was necessary to examine the injection site 4 to 6 weeks later. Many considered the need for a second negative skin test to be routine prior to beginning treatments, and even with a negative second skin test the likelihood of an allergic reaction was not entirely eliminated. In addition to a hypersensitivity reaction, bovine collagen injections can result in tissue necrosis (26), foreign body reactions (27) and infrequent systemic reactions such as headache, nausea and arthralgias.

In 2003, the FDA approved release of a bioengineered form of human collagen fillers (Cosmoderm, Cosmoplast—Allergan, Inc, Irvine, CA). The primary advantage of these was a longer duration of effect than bovine collagen, and because these products were derived from bioengineered human fibroblasts no skin pretesting was required. Like the bovine collagen fillers however and for similar reasoning, distribution of these has also been recently discontinued by the manufacturer. A technique for producing autologous collagen was introduced in the mid-1990s—Isolagen (Isolagen Technologies, Houston, TX)—as a way to inject patients with their own fibroblasts that were harvested, cultured, grown *in vitro* and then processed for use. The expense, the time factor in production, the complexity involved in the process and the need for precise coordination between manufacturer, doctor and patient proved to be impractical however, and for that reason the product is no longer available.

Hyaluronic Acid Products

Hyaluronic acid is the main polysaccharide in the extracellular matrix of the human dermis. Because it has the ability to bind 1,000 times its volume in water, HA confers a certain amount of turgor to the skin by affecting dermal volume and compressibility (28). HA is unique in that it is chemically the same in all species, and therefore its derivatives should not be antigenic across species. The injected product is enzymatically degraded locally and then metabolized by the liver into carbon dioxide and water.

HAs are the most widely used of all dermal fillers (29). Commercially available products vary with respect to the source from which they are derived, particle size, degree of cross-linking, viscosity and whether or not lidocaine has been added to the filler. The first HA gels introduced for cosmetic use were derived from rooster combs, whereas most HA products produced today are derived from a non-animal source. Smaller particles used more commonly for finer lines generally last 6 months or more, while larger particles last more in the range of 6 to 12 months. A higher percentage of cross-linking equates with increased resistance to enzymatic biodegradation and therefore a longer duration of effect. HA gels are injected into the mid- to deep dermis to effect a correction of moderate to severe facial wrinkles (Fig. 197.6A and B).

There are two salient advantages to the use of HA gel fillers as compared to collagen. The first is that since HA is identical across species the manufacturers do not recommend or require skin testing prior to injection. Nonetheless, although the current product is highly purified, there are still minute amounts of associated proteins (30). As a result, rare cases of localized hypersensitivity reactions resulting in local erythema and induration resolving in 4 to 20 weeks have been reported (31–33). Overall, the risk of an allergic reaction was less than 1%, and manufacturing processes have evolved to reduce the amount of protein present resulting in fewer reactions. The other notable advantage of the HA products is that in the event of adverse reactions including improper placement (location or

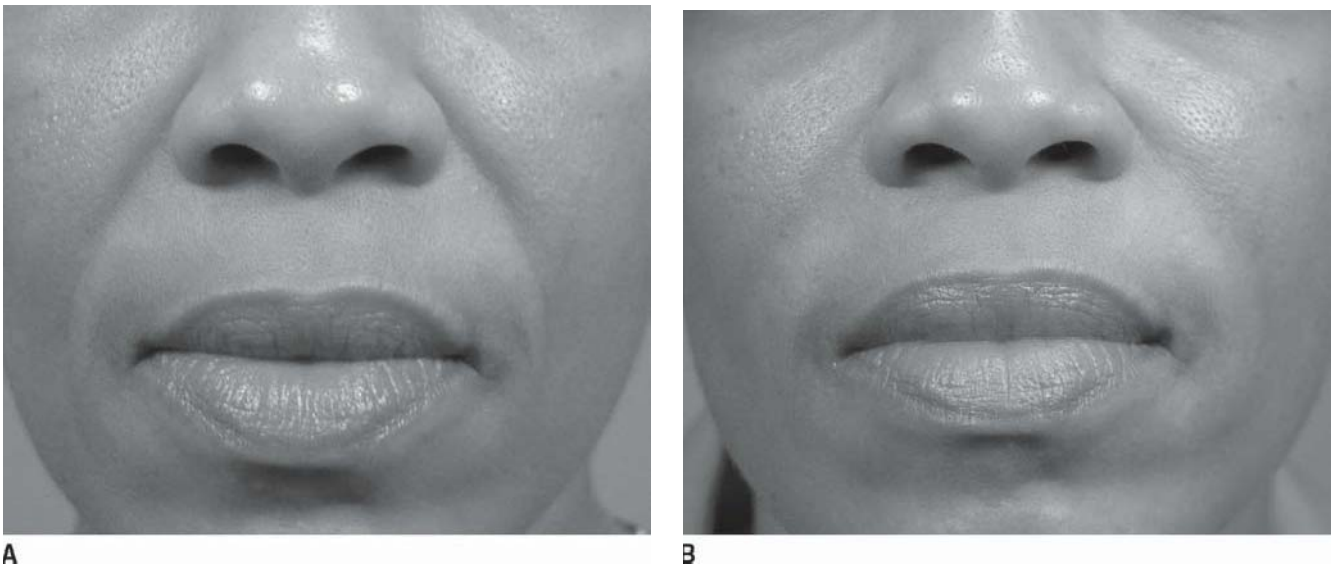

Figure 197.6 Before **(A)** and after **(B)** HA injections to melolabial creases.

volume), the gel can be enzymatically degraded with the use of injectable hyaluronidase giving these products the significant added benefit of being "reversible" (34).

Currently available FDA-approved HA fillers in the United States include Restylane and Perlane products (Medicis, Scottsdale, AZ), Juvederm products (Allergan, Irvine, CA), Prevelle Silk (Mentor, Irving, TX) and Elevess (Anika Therapeutics, Bedford, MA).

Calcium Hydroxylapatite

Radiesse (Bioform Medical, San Mateo, CA) is a biosynthetic polymer composed of 30% calcium hydroxylapatite (CaHA) microspheres (25- to 45-micron diameter particles) suspended in a 70% carrier gel made up of carboxymethylcellulose, water and glycerin. CaHA is naturally occurring component in human bone and teeth, and for that reason skin testing for allergy is not required. Radiesse is the only FDA-approved commercially available CaHA filler.

The FDA-approved cosmetic indications for the use of CaHA are for the correction of moderate to deep facial wrinkles and folds such as the nasolabial folds (Fig. 197.7) and for the treatment of HIV-associated facial lipoatrophy. Off-label facial cosmetic applications have included volume augmentation in the malar area, cheek and prejowl sulcus, marionette lines and nasal dorsal irregularities. Deeper folds are augmented with injection into the immediate subdermal plane, whereas volume augmentation (prejowl, malar) is generally done with supraperiosteal deposition of the product. Edema, erythema and ecchymosis are not uncommonly seen with Radiesse injections, but these adverse effects are temporary. Lidocaine can be safely added to the Radiesse syringes without having any deleterious effect on the qualities of the original filler material (35).

When injected, initial volume augmentation results from the displacement of surrounding soft tissue by the carrier gel and CaHA microspheres. Ultimately, the carrier gel undergoes phagocytosis while a process of stimulated neocollagenesis takes place around the CaHA microspheres which serve as a framework or scaffold for the ingrowth of new tissue (36). The duration of effect is typically 12 months or more. The combination of host neocollagenesis and the slow degradation of the CaHA microspheres are thought to account for the more prolonged duration of effect. CaHA is apparent within the soft tissue on CT imaging, but does not generally interfere with interpretation of the images (37).

Figure 197.7 Before **(above)** and after **(below)** CaHA (Radiesse) injections to nasolabial creases and marionette lines.

Poly-L-Lactic Acid

Poly-L-lactic acid (PLLA) is a biodegradable synthetic biopolymer already in use in suture materials and absorbable fixation plates and screws. The commercially available injectable product, Sculptra Aesthetic (Sanofi Aventis, Bridgewater, NJ), is supplied in a vial as a powdered form of PLLA microspheres in a carboxymethylcellulose gel that must be reconstituted with sterile water 2 to 72 hours prior to injection. Skin testing is not necessary.

The product is injected into the subcutaneous plane. The volume that is immediately apparent upon treatment dissipates over the first few days as the water used to reconstitute the powdered PLLA is resorbed. For this reason, the patient must be counseled accordingly so as not to be initially disappointed. Over time, the PLLA microspheres act by stimulating an inflammatory fibrous tissue response in the host that activates collagen neogenesis and deposition around the degrading PLLA particles (38). Several sessions spaced 3 to 4 weeks apart are typically required for complete volume restoration.

As the volume augmentation that occurs results from stimulation of the host to produce new collagen, the effect takes time and the patient should be made to understand that it is not immediate. Strictly speaking, PLLA is not a true filler but rather a collagen growth stimulator.

Sculptra was FDA approved in 2004 for the treatment of facial lipoatrophy in HIV patients, and Sculptra Aesthetic (essentially the same product) was FDA approved in 2009 for the correction of shallow to deep nasolabial fold contour deficiencies (Fig. 197.8). It has been used off-label as

Figure 197.8 Before **(left)** and after **(right)** PLLA (Sculptra) injections to temples, malar eminence and cheeks for the treatment of facial lipoatrophy.

for effective malar, cheek or temple volume augmentation. It is not recommended for use in the periorbital area or lips. The effect may last up to 2 years.

Adverse effects of particular concern with PLLA are the possibility of developing subcutaneous nodules or papules that can develop months after treatment. One can help diminish this risk by insuring an adequate volume of dilution (5 mL or more), preparation of the product at least several hours prior to its use for more complete hydration of the PLLA powder and having the patient massage the treatment area frequently for the first 5 days after each session.

Polymethyl Methacrylate

Injectable polymethyl methacrylate (PMMA), commercially available as Artefill (Suneva Medical, San Diego, CA), is a nonabsorbable permanent filler made up of a suspension of 20% PMMA and 80% bovine collagen. As the collagen carrier is absorbed over 2 to 3 months, the PMMA microspheres stimulate a foreign body reaction and collagen formation. The PMMA acts as a matrix or scaffold for the deposition of the tissue ingrowth, becoming encapsulated by fibrous tissue ensuring a constant augmentation (39).

Skin testing is required because of the presence of the bovine collagen antigens. Artefill was FDA approved in 2006 for the correction of nasolabial folds but has been used off-label for glabellar frown lines, marionette lines and radial lip lines. The material is injected at the junction of the dermal–subdermal junction.

With earlier preparations (used outside the United States), multiple foreign body granulomatous reactions were reported resulting in poor results and increased morbidity and scarring (40). Refinements to the product were made to lessen that risk and achieve the current FDA-approved preparation. Although the collagen vehicle is resorbed, the PMMA microspheres are non-resorbable and persist in tissue permanently.

Silicone

Injectable silicone is a permanent, non-resorbable filler composed of long chains of polymerized dimethylsiloxane oil. The technique of microdroplet injection was popularized by Webster et al. (41) and Orentreich and Orentreich (42). With this technique, very minute amounts (0.01 mL per injection site) of medical grade liquid silicone are injected into the subdermal plane at 2- to 4-mm intervals. Care is taken not to overcorrect the treatment area as the microdroplets stimulate fibroplasia, and the body thus forms a fibrous collagen capsule around the silicone microdroplets over the ensuing weeks, thereby augmenting the original volume of the liquid silicone microdroplet. Undercorrection is therefore the initial goal, with repeat sessions staged a month or more apart until the desired result is achieved.

Prior to the introduction of injectable collagen, liquid silicone was the filler of choice, although problems arose from products of differing purity, variations in technique and the lack of any standardized FDA-approved product. Webster et al. (41) reported a long-term follow-up with a series of 524 patients with good results and few complications, but others have reported a long list of local and systemic complications some of which may appear even years after injection. These reactions range from chronic inflammation, silicone granulomas, beading, migration, extrusion ulceration and skin necrosis to granulomatous hepatitis, pulmonary embolism and silicone pneumonitis (43–45).

In 1991, the FDA declared the use of injectable silicone illegal. However, with the recent FDA approval of injectable

silicone as an intraocular implant in ophthalmology for retinal detachments the off-label use for soft tissue augmentation has been revived. Off-label uses of injectable silicone remain controversial however because of the history of complications with injected silicone, and one must carefully consider the risks versus the benefits (46).

Autologous Fat

Autologous fat has the longest history of use since Neuber (20) first injected it in 1893. The interest in autologous fat transplantation has vacillated over the years due to the variability in results. Some investigators report that between 30% and 60% of the injected fat will be resorbed (47). However, since the advent of liposuction in the 1970s, interest in fat transplantation has increased. Over the last 15 years, techniques and instrumentation for the harvesting, preparation and injection of autologous fat have evolved to improve fat survival and diminish resorption thereby increasing the predictability of the procedure. Some authors such as Coleman (48) recommend injection of small amounts of fat in subcutaneous tunnels to maximize the amount of blood flow to the transplanted fat, thus increasing its viability and the chance of survival. Harvest of fat has to be gently performed with minimal syringe pressure using large-bore cannulas to minimize trauma to the harvested fat cells.

To date, there is no universally accepted method for the harvesting, processing and reinjection of autologous fat, and often results are not reproducible. The advantage of fat transplantation is the large amounts available in the human body, and because it is autologous and natural it negates the concern for allergic reactions and biocompatibility. On the other hand, fat transfer is a surgical procedure, has a more significant recovery period as compared to other injectable fillers and requires a donor site with its own set of potential complications. In addition, fat grafting has the disadvantage of having an unpredictable resorption rate, and touch-ups can be more involved than with off-the-shelf fillers. Over recent years, the surge in interest in commercially supplied dermal fillers has coincided with some decline in the number of fat injection procedures.

Complications of Injectable Fillers

While it is impossible to eliminate complications entirely, most experts will agree that serious complications are rare if the practitioner is committed to accurate facial analysis, proper patient selection and product choice, appropriate training for each filler used and diligent application of technique. Treatment must be individualized and tailored to the needs of the patient, and the limits of what can be accomplished safely must be respected.

While increased product longevity would seem to be a desirable characteristic, one should carefully weigh the risk/benefit of biodegradable, resorbable fillers versus permanent fillers. The fact that visible complications such as bumps, ridges or nodularity will ultimately resolve when a temporary filler has been used may provide some reassurance and comfort to a patient. This comfort level is not available to the patient who has been injected with a permanent filler. At the very least, one should avoid the use of permanent fillers in a given patient until that patient has already used something absorbable with good results.

Complications can be broadly classified into immediate, early, late and permanent. Immediate complications include anaphylaxis, hypersensitivity and pain. Early complications include bruising, edema, overcorrection, infection and vascular compromise. Later complications can include HSV activation, visible irregularities, lumps, granuloma formation and product migration. Permanent complications include scarring (49).

Edema, bruising and injection site pain are not uncommon sequelae and are not truly complications but rather known side effects. Ice packs or cold compresses applied to the treatment area as well as effort directed to avoiding inadvertent puncture of superficial vessels may be helpful in minimizing these.

Allergic or hypersensitivity reactions can theoretically develop with any filler, but are more likely to be an issue with those containing a bovine collagen additive (collagen, Artefill). For these fillers, skin testing is required prior to definitive treatment.

With all fillers, injection technique and proper depth of injection are paramount to success. Superficial injection can result in visible nodularity or lumps. Early-appearing nodules may respond to massage, and in some cases the overlying skin can be nicked and the product extruded (if apparent very early). More delayed appearance or visible nodules may improve by treating the area with small doses of locally injected steroids. HA fillers, if placed too superficially, can result in a bluish discoloration of the skin over the area of injection which is known as a "Tyndall effect." This may be treated with extrusion as noted earlier, or if that fails, the untoward effect HA fillers can be "reversed" with the use of injected hyaluronidase. Naturally, visible irregularities are a much bigger issue if one has used a permanent filler. With permanent fillers, persistent nodules may require surgical removal.

Soft tissue necrosis can occur with vascular compromise resulting from either direct intra-arterial injection or venous obstruction from compression exerted by the filler material. The areas at highest risk are the glabella and the nasal ala in the region of the alar–facial sulcus (medial end of the nasolabial crease). Signs of vascular compromise include blanching of the skin, disproportionate injection pain and discoloration of the surrounding tissue. Management should include immediate cessation of the injection, vigorous massage of the treatment area in an effort to disperse the filler, application of warm compresses and topical nitroglycerine paste for vasodilation and local injection of hyaluronidase (if an HA filler was used).

Conclusion

Although no ideal filler is yet available, very active research and development continues in this area of facial plastic surgery. There are many choices offered on the market that can fulfill patient's needs. It is incumbent upon every practitioner who uses fillers to stay informed on the current materials in order to better inform patients and to make the best possible choices. Often two or more fillers used in combination offer the best results. Likewise, it is not uncommon to combine botulinum toxin in the upper third of the face and fillers in the melolabial folds, marionette lines and perioral region to obtain a refreshed and rejuvenated appearance.

With any permanent synthetic filler, concerns will exist about potential long-term effects or delayed complications. Although permanent complications are uncommon, the wide array of biodegradable, absorbable fillers with favorable safety profiles and relatively predictable results is without doubt a safer alternative, particularly for the inexperienced injector.

As has been stressed throughout this chapter, successful use of both the neurotoxins and injectable fillers begins with familiarity with the strengths and limitations of each product, comfort with the nuances of injection techniques, accurate facial analysis, careful patient selection and realistic management of patient expectations. Properly applied, these minimally invasive nonsurgical techniques can be a valuable and powerful addition to the armamentarium available for the management of facial aging.

HIGHLIGHTS

- Botulinum toxin is used in the treatment of dynamic facial rhytids to prevent them from either developing or deepening.
- Botulinum toxin works by temporarily inhibiting presynaptic release of acetylcholine at the motor end plate. Its use is contraindicated in those with neuromuscular disease and albumin allergy.
- Familiarity with regional facial anatomy, proper technique, and the use of high concentration–low volume dilutions will minimize the risk of adverse outcome with botulinum toxin.
- Injectable fillers are used for soft tissue augmentation to add contour and volume. They are commonly used for camouflage of established facial rhytids and scars and for lip augmentation.
- A great variety of injectable dermal fillers are available. Proper selection will depend on region, patient preference and hypersensitivities.

Contemporary Issues in Medical Practice

Shawn D. Newlands *Karen T. Pitman*

Patient Safety 198

David E. Eibling

"Primum, non nocere" Attributed to Hippocrates (1).

Since the days of Hippocrates, it has generally been assumed that attempts to heal are unpredictable, and those attempts occasionally result in unintentional harm. Injury, and even death, were inevitable for a few unfortunate patients. Health care providers, patients, and the public judged that the natural history of the disease process itself justified these occasional undesired outcomes. When facing imminent surgical or other interventions, patients could only hope that they were protected by their choice of the best doctors and hospitals. Moreover, the statistical odds of themselves or their family members becoming a victim of an iatrogenic injury were small enough to offer some level of comfort. In essence, they relied on hope—hoping it was not "their turn" for something to "go wrong." Physicians likewise were well aware that medical care was imperfect, that diagnoses were sometimes flawed, and that treatment attempts were often poorly conceived, planned, and executed. The occasional medical mistakes were inevitable. Preservation of their own confidence and decision-making ability often relied on the assumption that mistakes were made by other, less able practitioners working in other hospitals and that they were protected by their superior knowledge and skills and superior institution. Many poor outcomes could, (and often were) with minimal effort, be attributed to the patient or their disease process itself.

Of course, not all adverse events that impact patients are due to mistakes. Patients can be harmed by "Acts of God," unforeseen circumstances such as weather or other anomalies that destroy hospitals and infrastructure (tornados, earthquakes, tsunamis, or hurricanes to list just a few from recent years), killing or injuring inpatients along with others in the affected community. Many adverse events, such as infections or falls, long assumed to fall into this "Acts of God" category, are now being shown to be preventable. The growing assumption is that *failing to prevent* potentially preventable harmful occurrences represents failure and can be interpreted as a mistake. The list of these events continues to increase as investigators demonstrate that interventions can impact the incidence of or harm caused by these occurrences. In recent years, new payment policies in the United States that withhold reimbursement for the treatment of such events add credence to the fact that errors of omission are also mistakes.

Mistakes judged as preventable were interpreted by both society and the medical establishment as indicative of the failings of individual providers who by definition must have been flawed in some way. The assumption that "someone caused this and they have to pay" fed a burgeoning tort claim system whereby the injured patient could seek restitution. The inevitability of human error occurring in the context of ever-increasing complexity and uncertainty led to the flourishing of the medicolegal industry, which grew dramatically in the last half of the 20th century. Accompanying the growth of this industry was wholesale proliferation of armament for the plaintiffs and their legal representation, driven by enormous increases in tort claim awards. Defensive measures were introduced, such as a malpractice insurance industry, often supported by legal mandate, and risk management strategies that sought to protect the health care industry, at the cost of considerable expenditures of resources. As of 2011, efforts to retard the growth of the medical malpractice industry by limiting the amount of financial rewards have been only minimally effective, suggesting that alternative strategies will be required. Shifting the current medical malpractice paradigm to one that improves care, like so many other needed cultural changes, has, by default, been relegated to future generations. The reader is referred to Chapter 199, *Medical Legal Issue*, of this book for a more in-depth discussion of medicolegal implications for otolaryngologic practice.

Contributing to this ongoing impasse is the culture of "name, shame, and blame," an inbred tradition in

which most physicians practicing today were trained. The assumption that most mistakes are due to flaws in individual physician performance conveys multiple costs to both the physician and his or her family and colleagues, as well as the organization in which he or she practices. This focus on the individual mandates the identification of the person responsible for the outcome, formal evaluation of his or her performance, and then restriction of his or her practice or enrolling the person in an educational program so that the error does not recur. At times the criminal justice system has been activated, with the result that health care workers who make mistakes are arrested with criminal charges, and even incarceration. Unfortunately, not only does this approach usually fail to identify and rectify the underlying problem, it impairs the objective analysis of human error and assures that the failure will occur again. Examples of misdirected peer review programs are prevalent in 2011 and challenge forward-thinking leaders who are attempting to prevent or mitigate future mistakes. With the exception of a few leaders in patient safety, this paradigm has persisted through the first decade of the current century.

Although these sentiments remain prevalent throughout health care, other industries have long recognized that focusing on individual practitioners is a failed strategy. These industries recognized that human performance is imperfect and highly context dependent, a recognition that drove the adaptation of their corporate structure to this "new" reality. Industries that modified their corporate culture and production systems to adapt to the abilities of their employees, rather than focusing solely on the performance of those employees, excelled in the marketplace due to reduced production costs. Gurus such as Shewforth (2) and Demming (3), initially eschewed by US industries, were embraced by the postwar Japanese, with dramatic results. The effect of this paradigm shift in Japanese industry became evident over the past quarter of a century as automobiles from Japan began to make major inroads into the US automaker's monopoly on the roads and highways of the United States. Medicine was late in accepting the premise that *context* mattered. The recognition that the environment and systems within which human practitioners provided care is a critical factor in outcomes and that it is possible to alter that context through informed system design is only slowly dawning on the industry. As of 2011, medicine was still struggling with the concept that imperfections in complex systems lead to the majority of preventable adverse events, with the focus on error prevention still largely focused on individuals (4,5). Dekker pointed out that this paradigm makes sense to leaders since there are institutional benefits to be had by focusing blame on individuals. Doing so relieves the organization from embarking on often difficult and costly change. *"The judgment that this was human error simply produced too many organizational benefits"* (6). Unfortunately, this strategy simply leads to repeated errors, a lesson learned long ago by other industries. Studying the aviation industry provides insight into the ongoing efforts of the patient safety movement as it attempts to change the entrenched culture of the health care industry (7).

HISTORY OF THE AVIATION SAFETY MOVEMENT

Aviation is generally considered the first industry to position safety as its top priority, a logical choice for the industry since aircraft crashes dramatically impact productivity through loss of not only the aircraft but also often the pilot as well! Following the Second World War (WWII), the United States Air Force (USAF) discovered to their dismay that no amount of pilot training would suffice to prevent crashes if the aircraft could not be safely flown by a human. The advent of jet aviation was met with a rash of accidents due to the increasing mismatch between the capabilities of high-performance aircraft and high-performance pilots. The USAF was instrumental in the development and maturing of the science of *human factors* in order to assess human capabilities during flight and to use this knowledge to inform aircraft design to accommodate to these capabilities. Formal investigation into the limits of human performance drove the development of the science of human factors, a discipline that informs system design to assure that the airplane can be flown by a real human. If the pilot becomes unconscious during a high-G maneuver, it does not matter how well the plane is designed; it will crash and be destroyed along with the pilot. Initial human factors research was directed toward human physiologic capability, such as performance characteristics under high G-forces, or alteration in pressurization and oxygen availability. It became apparent that cognitive resources were also challenged by high-performance flight, and that too little information, too much information, or information provided in a confusing manner would lead to accidents just as well as if the pilot had blacked out. This recognition drove the development of new cockpit information systems, and aviation became the "poster child" for "human-centered design" with reliability and safety as primary goals.

Despite dramatic improvements in aircraft design in the years following WWII, a number of high-visibility aircraft crashes in the 1970s pointed out vividly that even the presence of a highly skilled pilot in the optimally designed cockpit of a technically advanced aircraft could not always avert disaster. The loss of United 193 and Eastern 401 and the improbable crash of two loaded 747s on a fog-shrouded runway in Tenerife in March 1977 (8) were a wake-up call for the industry. Aviation came to the understanding not only that theirs was an imperfect system but that the industry must shoulder the responsibility of improving the system. Inherent in this understanding was the recognition that the established paradigms were untenable and that change was necessary—and the optimism

that such change was possible. As a result, multiple innovations were introduced in the 1970s and 1980s, which led to dramatic reductions in the aviation accidents. These include no-fault near-miss reporting, standardized simulator rehearsal, crew resource management (CRM) training (9), and rapid and widespread dissemination of information regarding safety threats (http://www.asrs.arc.nasa.gov. Accessed May, 2011). The most critical change, however, was the fact the industry embraced a "culture of safety" in which all employees are empowered—and expected—to respond immediately and report safety threats (7). Many of these cultural changes are being introduced into health care, but as of 2011, these are best described as "in process." Despite widespread encouragement (10), and although many organizations actively promote the concept of a "safety culture" and survey their employees to assure they are achieving their goals, medicine is still far behind aviation in this regard.

TO ERR IS HUMAN

Medicine was rudely awakened to the extent of the problem of medical error by the publication of the Institute of Medicine report "To Err is Human" published in 1999 (11). This report estimated that somewhere between 44,000 and 98,000 Americans died each year in hospitals as a direct result of medical error. Based on the Harvard Medical Practice study (12) published nearly a decade previously, the figures in the report were initially strongly disputed. It seemed impossible that the same number of deaths occurred each day due to medical errors as would be caused by two 747 crashes *each day*. It has since become apparent that even the 98,000 figure is a gross underestimate of the true magnitude of the number of deaths due to medical error. The numbers are staggering, with the current best estimate is that 1 in 20 Americans will die due to a medical error. Medical mistakes account for the eighth most common cause of death in the United States, more than deaths due to HIV and breast cancer combined! The economic costs are staggering, with a recent estimate that the total societal cost of health care–related adverse events in the United States is now approaching a trillion dollars annually (13)!

Our knowledge of the fundamental science behind medical error is based on the work of psychologists such as James Reason (14) who undertook to determine why humans make mistakes. The research into this area is immense and has recently been recognized by the health care industry as pertinent to an understanding of medical error. Reason classically separates human error into two major types, that of a *mistake*, which is choosing the wrong plan to achieve a specific goal, or a *slip*, which would be defined as failing to execute the plan that one has chosen. Ordering an antibiotic to which the responsible organism is not susceptible might be a mistake, and picking the wrong vial out of the medication drawer might be a slip. Human error is inevitable as illustrated by the title of the 1999 IOM report "To Err Is Human." Human error is a *by-product* of human attributes, which enable humans to interact with a complex, perceptively rich world. Human error stems from the same cognitive functions that enable the filtering of sensory input, focusing attention on specific goals, pattern recognition, and sequencing of events. Reason quotes Ernest Mach who eloquently stated "accomplishment and error stem from the same source, only the outcome differentiates the two" nearly a century earlier. Other disciplines, particularly those focusing on studying human factors, have adapted these principles through "cognitive engineering" to design strategies whereby the human–technology interface can be improved to reduce the propensity for human error (15).

"PREVENTION" OF HUMAN ERROR

Those who have assimilated the prior paragraphs will quickly recognize that the title of this section is inaccurate. Human error, by its nature, is not preventable. Helmreich (9) pointed out that the goal of error prevention is actually the prevention of injury. He proposed the term *"error troika"* as a fundamental concept useful in designing systems with the goal of injury (or crash) prevention. Errors will happen, but it is possible to design systems to (a) reduce the likelihood of error, (b) "trap" the error before it can progress, or (c) mitigate or prevent the effect of the error once it has occurred. Medication administration strategies often seek to employ all three components of the "troika," with variable success. In a similar vein, the famous "Swiss Cheese" illustration of Reason (14) points out that well-designed systems have multiple layers of protection, or barriers, placed between the error and the "target." These barriers vary in permeability, however, and typically have "holes" that reduce or negate their effectiveness. Whenever the "holes" line up, the effects of the error are experienced by the "target." Keeping this illustration in mind as the reader peruses the examples of safety innovations in this chapter will assist in developing new strategies to protect patients from the unintended actions of well-meaning health care workers.

HISTORY OF THE PATIENT SAFETY MOVEMENT

The seminal article by Lucian Leape published in 1994 (16) was the first to clearly identify medical error as a cause of adverse outcomes in health care. Dr. Leape made a number of pertinent observations, critically by noting that although human error was inevitable, it did not occur randomly. In his paper, he drew heavily on the work of Reason and others, and nearly two decades later, his observations remain critical to our understanding. The concept that error was not random was a particularly crucial observation since it suggests that types and sites of error are *predictable*. Experience

in other industries (notably aviation) had demonstrated that prevention of accidents or their sequela was feasible by first investigating accidents that had occurred and using the knowledge gained to inform system redesign. At the time of Leape's report, the Aviation Safety Reporting System (ASRS) (http://www.asrs.arc.nasa.gov) had already been in place for 18 years and had already effected major changes in aviation. Leape pointed out that it was only by studying adverse events in an attempt to identify patterns and discern the causes could future events be prevented or mitigated. Furthermore, Leape emphasized the importance of reporting by frontline staff. Thirty years prior to the publication of "Error in Medicine," Shimmel, chief resident at one of the Yale-New Haven Hospitals, introduced the concept of systematically reporting all adverse events occurring on his inpatient service in an effort to identify and categorize the underlying causes with the ultimate goal of prevention (17).

Anesthesia was the first medical specialty to seek to systematically study medical error. In the late 1970s, faced with mounting public awareness of the risks of anesthesia, the American Society of Anesthesiologists sought to study the problem. The Anesthesia Patient Safety Foundation (APSF) was founded in 1985 and chartered to study anesthesia mishaps and propose interventions, http://www.asahq.org/For-Healthcare-Professionals/Patient-Quality-and-Safety.aspx. The APSF introduced what was at the time a revolutionary approach, the study of "closed claims" in which injured patients or their families had been compensated for an anesthetic adverse event. The story of how a single malpractice insurance company was induced to release this proprietary information (which could have been damaging to its profitability) is one of the intriguing success stories of patient safety and illustrates vividly the effect one or two individuals can make!

The APSF closed claim study (18) revealed that fully one-third of the events that had resulted in a payment to the plaintiff (closed claim) were due to a respiratory cause. This finding prompted the emphasis on the development of new technology (pulse oximetry and capnography) as well as difficult airway algorithms. Astonishingly, within a period of less than 6 years following the report of the APSF and dissemination of its findings, a substantial reduction in the incidence of perioperative respiratory events was reported (19). The success story of the APSF should be viewed as justification to dedicating sufficient resources to identify and study adverse outcomes as the first step in reducing the risk of medical mistakes or the effects of those mistakes.

The National Patient Safety Foundation was established in the 1990s, as a result of a major conference convened in 1996 to address the issues of patient safety (http://www.npsf.org. Accessed May, 2011). This conference brought together members of both the medical community and the human factors communities and was perhaps the first time that the mismatch between the complexity of health care and human capabilities was identified as the fundamental cause of medical error.

Largely unheralded outside of the specialty, it was not until the IOM report in 1999 that the previously unrecognized epidemic of death and injury occurring during medical care reached a level of awareness sufficient to promote action. The IOM report galvanized the nation and prompted the institution of a wide range of investigation and interventions. To quote Robert Wachter (5), "in short, everywhere one looked, one found evidence of major problems with patient safety." The IOM followed with additional reports, new organizations and government agencies (Agency for Healthcare Research and Quality [AHRQ]) were established, and hospitals established patient safety offices to address the issues at the facility level. The Veterans Health Administration (VHA) established the National Center for Patient Safety (NCPS) at Ann Arbor, appointing James Bagian, prior astronaut–physician, as its first director. The NCPS was the first system-wide effort to capture and study adverse events and institutionalized patient safety efforts within the VHA nationwide (http://www.patientsafety.gov. Accessed May, 2011). The state of Pennsylvania established a state level safety agency in 2002 (20) and Congress passed the Patient Safety and Quality Improvement Act in 2005 (available at http://www.govtrack.us/congress/bill.xpd?bill=s109-544. Accessed July, 2011).

Others, such as Peter Pronovost from Johns Hopkins, were unwilling to accept "business as usual" and initiated interventions based on the "basic science" of studying adverse events and near misses. Within a decade, challenges that had been previously assumed to be inevitable and unmanageable, such as hospital-acquired infections such as methicillin-resistant *Staphylococcus aureus* (21) and central line infections (22), were successfully tackled by patient safety investigators. These innovators studied the problems, formulated hypotheses, instituted new practices, and, in these examples, demonstrated remarkable success. It is instructive to note that investigations in patient safety do not follow the classic randomized clinical trial paradigm (RCT) since to do so may be unethical. Rather, most patient safety innovations follow the "*Plan, Do, Study, Act*" paradigm through which innovations are "tested" in actual practice and then studied prior to widespread dissemination and implementation.

The Joint Commission (previously known as the Joint Commission on the Accreditation of Healthcare Organizations) adapted new patient safety goals (JCPSGs) that are updated on a yearly basis and served as criteria for assessing hospital performance in patient safety. Essentially all hospitals in the United States utilize the JCPSGs as a roadmap for improving patient safety in their institutions (http://www.jointcommission.org/assets/1/6/2011_NPSG_Hospital_3_17_11.pdf. Accessed May, 2011). Reviewing these goals is an effective strategy to identify what the organizational targets in patient safety are at any specific time.

Despite these and many other innovations, as of 2011, the epidemic of errors continues to extract an unacceptable toll, both human and financial. In a classic editorial in Health Affairs, "The IOM report: 10 years later" Carolyn Clancy, Director of AHRQ, pointed out that painfully little had occurred, primarily due to an inability to change an intransient culture (23). The rest of this chapter reviews a number of concepts and interventions to guide the otolaryngologist who is beginning his or her "safety journey." The reader will hopefully identify some achievable targets that can be utilized by otolaryngologists, health care teams, and enterprise organizations to reduce the risk of harm to the patients entrusted their care.

SAFETY AND QUALITY

Confusion often exists in defining a perceived boundary between the definitions of *quality* and *safety*. In reality, the boundary is indistinct, although safety can be considered as a prerequisite for quality (5). High-quality care is assumed to be effective care, typically defined by favorable clinical outcomes coupled with cost-effectiveness, usually compliant with established guidelines when such guidelines exist. However, to be high quality, care must, by definition, first be *safe*! Poor quality or ineffective care might be safe, but if the care fails to halt disease progression, one can argue that it is by nature unsafe. A leader in patient safety is reported to have quipped that "*50 years ago healthcare was safe, cheap, … and ineffective, whereas now it is effective, expensive, … and dangerous*," implying that the complexity required to increase effectiveness of intervention paradoxically increases the risk for injury. Most would assert that the risk is worthwhile. For example, undertreatment of a malignancy to reduce the risk of complications to zero is not desirable since the patient may lose years of valuable life. Regardless of the definition of quality, there are some inherent differences in the strategies employed; quality has the goal of effecting an optimal outcome for the patient, whereas safety seeks to prevent causing harm while doing so.

MEDICAL ERROR AND SYSTEMS SCIENCE

Understanding the causes of medical error requires an in-depth examination of *systems*. Systems consist of people, technology, policies, coordination, and other strategies intended to result in a desired outcome. An aircraft flight occurs due to a closely linked system of the aircraft itself as well as its crew, but also the maintenance and ground personnel and equipment, scheduling, routing, weather, and a plethora of interrelated functions. Systems science has been highly defined in other industries, but only recently has received attention in health care, which by its nature consists of multiple overlapping highly complex systems. Roberson and coauthors emphasized the importance of critically examining whole systems when analyzing processes of care and how these processes affect patient outcomes (24). "Systems-based practice" represents one of the six core competencies as defined by the Accreditation Council for Graduate Medical Education and the concepts are familiar to all otolaryngologists who have trained in the past decade. Some of the basic principles of systems are well defined and include the principles enumerated in Table 198.1.

TABLE 198.1 CHARACTERISTICS OF EFFECTIVE COMPLEX SYSTEMS

Common goal for all system components
Goal-driven system design
Unpredictability expected
Expect and accommodate human error
Feedback loops with short cycle times
Standardization is baseline
Reliant on teams rather than single individuals

From Roberson DW, Kentala E, Healy GB. Quality and safety in a complex world: why systems science matters to otolaryngologists. *Laryngoscope* 2004;114:1810–1814.

ACCOUNTABILITY AND "JUST CULTURE"

The emphasis on system design as the underlying threat to patient safety shifts the attention from individual performance to system performance. Although this shift is more likely to lead to prevention of adverse events, it has been construed by some to mean that the individual shares less responsibility. This conflict has been addressed at a high level within the aviation industry through the adoption of "*just culture*" (25). A *just culture* recognizes that expert practitioners (i.e., pilots or physicians) typically must accommodate multiple goals, such as keeping on a flight schedule and avoiding stormy weather conditions. In order to perform at high levels, these practitioners must possess some degree of flexibility in order to satisfactorily resolve conflicts and achieve desired outcomes (26). However, within each profession, there exist boundaries within which accomplished practitioners remain. These are often well recognized within the profession, even if not discretely defined by policy or written procedures. Performing outside of these boundaries is not an inadvertent human error but is an intentional act and considered "reckless behavior." In a seminal report published in 2001, David Marx has emphasized that these boundaries must, by nature of their significance, be defined by the profession itself (27). In aviation, an example would be completion of the preflight checklist; examples in surgery include the universal preprocedure pause for "time out" or completion of a postoperative sponge count prior to wound closure. Just as pilots would never consider initiating a flight without completion of the checklist, surgeons would never

consider initiating a surgical procedure without first doing a "time out" or closing the wound and leaving the operating room without a reconciled sponge count. In both settings, individuals function within teams that help assure that "forgetting" to do so is extremely unlikely. Refusing to comply with expectations of the profession after being reminded would be considered "outside the norm" and "reckless behavior" and place the practitioner at risk of censure.

Practitioners are also responsible for the systems within which they work. The level of accountability varies by the level of administrative responsibility, but even house staff bear some responsibility and must assume partial "ownership" of the systems in which they work (28). One way in which practitioners can participate in system improvements is by identifying threats to safety, reporting, collecting, collating, and assessing these threats, then develop interventions to reduce them. The challenges are immense, beginning with the task of identification and reporting.

MEASURING PATIENT SAFETY

"Safety shows itself only by the events that do not happen"—Erik Hollnagel

The adage "if you can't measure it, you can't improve it" has been proven correct throughout all of science. Fundamental changes in health care did not begin until pioneer surgeons began assessing their outcomes in an effort to determine whether they were, in fact, effecting positive change for their patients. Over the past several years, a plethora of metrics for quality (although painfully few in otolaryngology) have been introduced, impacting essentially all of health care in the United States (http://www.cms.gov/qualitymeasures. Accessed May 18, 2011). However, few metrics exist to assess patient safety. Attempts to identify differences in outcomes are challenged by the heterogeneous nature of patient selection, institution, treatment and modality, collecting metric, and comorbidity. Nearly 20 years ago, the VHA attempted to measure surgical outcomes to the institution of a risk-adjusted morbidity and mortality (M&M) measure now referred to as Veterans Administration Surgical Quality Improvement Program (VASQIP) (29). An almost identical voluntary program termed National Surgical Quality Improvement Program (NSQIP) (the term originally referred to the VA program well into the first decade of the 21st century) is now managed by the American College of Surgeons. VASQIP and NSQIP measurement systems all involve chart review by trained personnel who attempt to quantify not only outcomes but also comorbidities to assess relative risks. Statistical adjustments are then made utilizing the relative risk to report a "risk-adjusted" outcome in which observed postoperative adverse events are compared with a risk-adjusted "expected" outcome. Although not sufficiently granular to facilitate identification of specific safety threats, use of the data has been demonstrated to drive improvements in quality and safety within the VA (29). Data entry relies on standardized training of reviewers, who vary nonetheless as they are human. As a result, even with standardized data parameters, variation is introduced into the measurement system. Newer electronic data mining may have the potential to reduce this variability; however, as Pronovost noted in a commentary in 2011 (30), current systems demonstrate substantial variability even when utilized to assess outcomes with an identical patient population. Moreover, although these risk-adjusted measures assume that adverse outcomes are due to suboptimal care or frank medical error (since they assume the risk-adjustment calculations remove patient comorbidities from the result), it is usually impossible to identify the specific events leading to the adverse outcome. For example, a specific episode of postoperative pneumonia might be due to inadequate nursing care with missed opportunity for chest percussion, deep breathing, etc., due to oversedation on the midnight shift, or due to reliance on pain medication technology that was ill suited for the patient for which it was utilized. Or was the occurrence secondary to the primary disease process that the risk-adjusting calculations failed to adequately measure? Quantifying medical error remains an enigma, one that will persist throughout the careers of all currently in practice or in training.

"NEVER EVENTS"

There exists a subset of medical errors that are so egregious, such as amputating the wrong leg, that their identification is straightforward and they are easily identified as errors, even by lay persons. Termed "never events" (as they should "never" occur), these errors, such as retained foreign bodies in surgery, wrong-site surgery, operating on the wrong patient, etc., are unambiguous mistakes. The list of never events, proposed and maintained by the National Quality Forum (http://www.qualityforum.org), currently contains nearly 30 "events." "Never events" are monitored though legally mandated reporting by many states, such as Pennsylvania, which enacted a formal Patient Safety Authority in 2002 (20). An obvious side effect of mandatory reporting is public disclosure, with its attendant institutional public relations challenges. Such mandatory reporting may dramatically impact public opinion, although hospital public relations offices can find comfort in the fact that their competitors are also required to report! However, even in the presence of mandatory reporting, severe adverse events and deaths are often successfully "hidden" from public view, particularly when encountered in a public relations risk–adverse medical environment. The Los Angeles Times reported in November 2010 that 87 hospitals had failed to report a single error in 3 years to the State of California (available at http://articles.latimes.com/2010/nov/27/local/la-me-hospital-errors-20100028. Accessed July 25, 2011). Unfortunately, hiding such information carries with it the risk that if and when the event is discovered the allegation of cover-up (rather than sloppy

record keeping) may receive even greater public scrutiny than the error itself.

Implied in the wrong-patient events are patient identification errors, which are considered by many patient safety authorities to be the most common unreported error in health care systems. Some impact of this error can be found in the fact that assuring correct patient identification has been one of the highest priority patient safety goals for the JCPSGs for several years. Although identification errors are common, they only become "never events" when the error results in serious injury to the patient.

Based on the challenges of identifying medical errors (with the exception of "never events"), detection of "surrogate markers" has become the *de facto* strategy utilized to assess patient safety. These include strategies that access electronic health records using data such as bar code medication administration (BCMA) records critical "drug–drug interaction" alert overrides, or rapid switch of prescribed medications. Classen et al. (31) estimated that use of automated triggers will increase the number of detected errors by 10-fold. Although these triggers add sensitivity, they also reduce specificity, so that expert review is often required. An example is identifying patients for whom perioperative antibiotics were not utilized when indicated (part of surgical quality performance measures). The trigger can detect who did and who did not receive perioperative antibiotics but is unable to identify which particular patients require prophylaxis.

ERROR AND NEAR-MISS REPORTING

Voluntary reporting has been consistently demonstrated to be insufficiently sensitive for accurate detection of medical mistakes and adverse events. In a classic study comparing the use of a formal chart review system (the American College of Surgeons National Quality Improvement Program) with standard reporting in M&M conferences, Hutter and colleagues noted that less than one-half of significant complications were reported at the M&M conferences. In a classic quotation, the authors expressed their surprise at their findings: *"we were surprised at our findings as we had always prided ourselves on the veracity of our M&M reporting system"* (32).

Pronovost and Lueford in their recent publication on improving reporting systems made five specific recommendations to improve the current status of reporting (Table 198.2) (20). In the author's opinion, of their recommendations, the most critical, and yet the one least likely to occur, would be the establishment of an independent agency. As noted earlier in this chapter, aviation was able to dramatically improve reporting of near misses by seeking to eliminate the "name, blame, shame" attitudes engendered by most high-performance systems. One critical attribute of the ASRS is that its oversight was assigned to an independent agency within the National Aeronautics and Space Administration (http://www.asrs.arc.nasa.gov. Accessed July 19, 2011) rather than the licensing agency, the Federal Aviation Administration. It was apparent to those setting up the system that inducing pilots to report their mistakes to FAA would be a doomed strategy since to do so could place the reporter's career in jeopardy.

TABLE 198.2 FIVE RECOMMENDATIONS TO IMPROVE REPORTING SYSTEMS

1. Assure validity and transparency
2. Standardize surveillance systems
3. Trend performance change over time
4. Develop strategies to prioritize measures
5. Create an independent agency

From Pronovost PJ, Lilford R. A road map for improving the performance of performance measures. *Health Aff (Millwood)* 2011;30:569–573.

Studies of medical mistake reporting systems have confirmed that the reporting system itself is often the culprit in reducing the likelihood of reporting by frontline staff (33). Some of the ways in which these systems fail are listed in Table 198.3. One of the more important factors that discourage reporting is the sense of fatalism held by many (most) health care workers: *"why should I bother to report since nothing is going to change?"* Until this assumption is replaced with a "can-do" assumption, it is unlikely that frontline reporting will increase. It can be anticipated that the readers of this chapter will have substantial opportunities to impact this assumption through their interaction with, or even design of, these systems in future years.

As of the second decade of the 21st century, no simple straightforward solution to measuring safety has been identified. The wide range of patient diseases, comorbidities, and treatment algorithms create a complex matrix that defies discrete measurement. As Pronovost and Lueford (30) note, "Let us hope that the efforts in the next decade embrace science instead".

TABLE 198.3 RULES FOR DESIGNING REPORTING SYSTEMS

Improve system usability and reduce inefficiency so that reporting fits easily into workflow
Define purpose of system for potential reporters, and be certain they can access and utilize it within their workplace
Reduce likelihood of adverse consequences by assuring confidentiality
Assure usefulness of reporting by providing feedback and eliminating "black hole" effect

MEASURING SAFETY IN OTOLARYNGOLOGY

Several investigators have reported on the prevalence of safety issues in otolaryngology. The premier report in this regard was a questionnaire sent to 2,500 otolaryngologists in 2003 with the simple question, "Do you know of a medical error in your practice within the past 6 months?" (34). Four hundred and sixty-six (18%) of surveyed otolaryngologists responded, and of these nearly one-half (210) knew of an error that had occurred. Of these, 78 or 37% had resulted in harm and 9 had led to the death of a patient. Using their findings, the authors estimated that roughly 2,600 patients are injured annually by medical errors in otolaryngology practice in the United States and that these errors lead to 165 deaths. Their estimates were plausible since they were congruent with the order of magnitude of the 1999 IOM report. Based on their findings, the authors proposed a classification system for reporting errors in otolaryngology, which can be summarized as listed on Table 198.4.

Additional studies focusing on specific threats in otolaryngology have addressed a number of threats uniquely encountered within otolaryngology. One of these is *recurrent* angiotensin-converting enzyme inhibitor (ACEI)–induced angioedema. Represcribing an ACEI following a prior episode of ACEI-induced angioedema is an obvious medication error, and despite its improbability, in the review by Roberts and coauthors, had occurred 26 times in a decade in a large academic medical center (35). We revisit this study later in this chapter and review possible strategies to reduce the probability of the event.

Another rare but potentially devastating error is the inadvertent use of concentrated medications. Although the (repeated) inadvertent administration of concentrated heparin to neonates *in lieu* of a lower dose for intravenous flush received the greatest attention (following the accidental overdose of actor Dennis Quaid's twins in 2007), in otolaryngology, the most devastating has been the inadvertent injection of concentrated epinephrine (1:1,000 or 1 mg/mL). The concentrated epinephrine errors are particularly instructive and are discussed in some detail.

In 1995, a 7-year-old boy died after mislabeled concentrated topical epinephrine was inadvertently injected during routine otologic surgery (http://www.ismp.org/newsletters/acutecare/artoc;es/19961204.asp. Accessed July 19, 2011). The sad case received widespread attention throughout North America, and its effect on the providers was featured in the instructional video "Beyond Blame" (available for purchase at http://www.onlinestore.ismp.org). The Joint Commission as well as the Institute for Safe Medication Practices (ISMP) have made specific recommendations intended to reduce the likelihood of similar events occurring, including expressing the concentration of critical medications as milligrams (mg) per milliliter or cubic centimeter (cc) rather than as a ratio (i.e., 1:1,000 epinephrine should be labeled as 1 mg per 1 mL) and requiring clear labeling of all medications, particularly on the "back table" in the operating room (OR) suite. Shah et al. (36) addressed the incidence of erroneous injection of concentrated epinephrine (1 mg per 1 mL rather than the intended 1:100,000 or 1mg per 100 mL concentration) in a survey of otolaryngologists reported in 2008. Of the 126 otolaryngologists who responded the survey, 34, or more than a quarter, had either personally experienced or heard of an epinephrine error *within the past year*, including five deaths. Sixteen, or one in eight, had personally experienced an epinephrine mistake within the past year, and 48, or more than a third, had experienced such an error in their careers (averaging nearly 20 years). Based on their experiences, many otolaryngologists introduced strategies, such as adding a few drops of methylene blue to concentrated topical epinephrine to alert the surgical team. Shah et al. make specific recommendations to prevent or reduce the occurrence (Table 198.5), although anecdotal experience suggests that these errors are still occurring in 2011.

TABLE 198.4 CLASSIFICATION OF ERRORS IN OTOLARYNGOLOGY

MEDICATION ERRORS

Errors in the administration of concentrated epinephrine or heparin, or ACEIs, are only the tip of the enormous problem of medication error. The pervasiveness of medication errors and the associated costs are staggering. The average hospitalized patient can expect to experience one medication error *each day* they are hospitalized, and the estimated cost of managing medication errors in the elderly is estimated to cost Medicare more than a billion dollars per year. The Institute of Medicine released a report in 2006 as part of the Quality Chasm Series that addressed the extent of the problem and outlined strategies useful for prevention (37). Rosenwasser et al. surveyed otolaryngology residents and attending surgeons operating in a single institution for a 2-month period in 2008 to seek to determine the incidence of perioperative medication errors. Twenty errors were reported occurring in association with a total of 589 surgical procedures. They noted a wide range of error types in their sample, with approximately one-half involving antimicrobials. The authors noted that the fast pace of care seemed to facilitate the mistakes. They made a number of recommendations, many of which relate to information access (38).

AGENCIES AND ORGANIZATIONS

An enormous and ever-growing number of public and private organizations are studying medical mistakes and seeking solutions to the challenge they present. Several organizations have assumed leadership positions in recommending specific interventions. These include the National Quality Forum, the National Safety Foundation, The VA NCPS, as well as AHRQ. The list grows dramatically, and an otolaryngologist could devote her entire waking hours to searching the Internet for information and still access only a small percentage of available information. Some of the sources the author has found useful are listed on Table 198.6.

RESPONDING TO MEDICAL ERROR

Adverse events, many of which are due to medical mistakes, will inevitably occur. Acceptance of this truism leads to the realization that all health care workers, including otolaryngologists, will all experience medical error. It is unlikely that anyone reading this chapter has not encountered medical error in their previous experiences. Poignantly, some have, or will, also experience error from the perspective of the injured patient or family member. Failure to address medical error, regardless of where or how it occurs, or is likely to occur, is unacceptable. Adverse events, in particular those due to error, require a response. Responses may be either productive or counterproductive—and unfortunately the latter often prevails (39). Many in the patient safety arena have addressed the counterproductive responses that are still common in the health care system. The reader is referred to the story of Eric Cropp, an inpatient pharmacist from a children's hospital, who was convicted of manslaughter and sentenced to jail for a medical mistake made by a technician he was supervising (story and commentary available at http://www.ismp.org/Newsletters/acutecare/articles/20091203.asp. Accessed July 22, 2011).

ROOT CAUSE ANALYSIS

Examining errors is the critical first step in effecting substantive changes in health care system functions that threaten safety. A standard technique is to perform a detailed analysis, often termed "*root cause analysis*" or RCA. The term is a misnomer since there is rarely only one cause, nevertheless, when done well, the exercise can inform leadership regarding potential interventions. When done poorly, it gives the illusion of effectiveness without altering risk for future patients. All physicians should be familiar with the strategy, since they will be inevitably involved at some time in their career. The Veterans Administration NCPS has been a leader in this regard (40) and has prepared a number of tools that are available on their Web site (http://www.patientsafety.gov.

TABLE 198.7 ROOT CAUSE ANALYSIS (RCA)

RCA Goals

1. What happened?
2. Why did it happen?
3. What can be done to prevent it from happening again?

RCA Strategies

What?

1. Interview frontline staff
2. Assemble chronology of event, attempting to avoid hindsight bias
3. Outline events and chronology on flow diagram

Why?

4. Consider causation
   a. Information systems
   b. Architecture
   c. Policies or procedures
   d. Equipment
   e. Environment
   f. In-place safety mechanisms
5. Rules of causation
   a. Clear cause–effect
   b. Specific descriptors
   c. Identify preceding cause, not human error
   d. Identify cause of policy/procedure violation
   e. Failure to act only causal if preexisting duty to act

How to prevent?

6. Actions may be strong or weak
   a. Strong actions: architectural, equipment design, forcing functions, interlocks
   b. Weaker actions: double checks, training, new policies
   c. Intermediate actions: workload modification, read-back, documentation, redundancy

From National center for patient safety. http://www.patientsafety.gov.

Accessed July 22, 2011). Some of the key components of an RCA are outlined in Table 198.7. Other resources include the "How to" guide by Sidney Dekker (41), which should be read by all who investigate medical errors. Others have addressed one of the biggest challenges, that is, of so-called "hindsight bias," which must be factored into conclusions reached by all who address human error (42).

OTOLARYNGOLOGIST RESPONSES TO MEDICAL ERROR

In 2006, Landers et al. reported the responses of otolaryngologists from the sample reported earlier by Shah et al. (34). They noted that most otolaryngologists had responded in some manner, and much of the reported data were offered voluntarily by the respondents. One-half had intervened to ameliorate the effect of the error on the patient, in approximately a third the event had resulted in a change in department or hospital practices, and a few (7%) had altered their own individual practice style. Ten percent noted that they had experienced guilt with an associated emotional response, and approximately the same percentage had disclosed the error to the patient (43).

THE SECOND VICTIM, DISCLOSURE, AND APOLOGY

As Lander and others (44,45) have noted, medical error impacts more than the patient and his family. In addition to the obvious medicolegal implications, physicians in particular may be emotionally devastated by medical errors they commit to the point they may become impaired by their response to the error with sleep loss, inability to focus, and secondary effects on their families and coworkers. Wu (46) has famously identified this paradox as the "second victim" and notes that the physicians and other health care workers who commit the error also need assistance in order to return to optimal levels of performance. Wu makes specific recommendations for strategies whereby one can assist coworkers faced with the emotional trauma of committing a medical error.

It is axiomatic that focusing on individual performance, attempting to cover up mistakes, and an institutional priority of protecting the health care team or institution by pulling down a veil of secrecy fails. Not only does this strategy fail to resolve the system design issues that led to the event in the first place, it will most likely exacerbate the negative effects of the error itself. Data exist to suggest that tort claims are often initiated by injured patients and families when they perceive dishonesty or cover-up on the part of the physician, team, or institution. The claim may be initiated "to find out what really happened." When evidence of an error is discovered, the assumption is often that the "doctor must be guilty since (he) tried to cover it up." A considerable body of knowledge exists that supports the benefit of early, honest disclosure to all parties (with the notable exception of tort lawyers). Honest disclosure should be considered integral to ongoing medical care of the patient, as such disclosure will help guide decision-making (47). The effect of disclosure on reducing the risk of tort claims has been well demonstrated, and a number of states have (as of 2011) introduced legislation that offers some degree of protection to health care workers and institutions that disclose errors. The VA has been a leader in this regard, and substantial resources are available online, with the Massachusetts Coalition guideline "When things go wrong: responding to adverse events" particularly useful (available at http://www.macoalition.org/documents/RespondingtoAdverseEvents.pdf). It has been noted that patients expect, and benefit from, an authentic and heartfelt apology as well as full disclosure of the facts. Although difficult to do since doing so is counter to the usual cultural traditions, apology should be considered integral to any response to medical error. Not only does physician acceptance of responsibility and apology assist the patient in "moving past" the error, but it also empowers the physician to engage in actions to improve systems to reduce

the likelihood of recurrence of the event. Excellent texts are available to assist the physician faced with the need to disclose (48), and the author has found rehearsal to be valuable in preparation.

SPECIFIC SAFETY INTERVENTIONS

The list of specific patient safety interventions that have been introduced is lengthy and growing at an exponential rate. By the time this chapter has reached publication, much of it will undoubtedly be out-of-date. The following section is not intended to be comprehensive but should be viewed as an overview. The reader is encouraged to seek additional information from the list of Internet sources in Table 198.6.

MEDICAL DEVICE SAFETY

The dramatic increase in the number and complexity of medical devices has added substantial increased risk of medical errors. Although some of these are due to failed automation or function on the part of the equipment itself (particularly noteworthy are the deaths due to programming mistakes in the Therac-25 linear accelerator), most device-related errors occur at the human–device interface. Essentially, instruments that were designed to assisting those seeking to cure may paradoxically occasionally facilitate errors by those same individuals. Among the early investigations into this paradox were the studies by Cook et al. into infusion pumps and other medical devices extending back to the early 1990s (http://www.ctlab.org. Publications accessed July 22, 2011). In the intervening years, the Food and Drug Administration has taken an active role in oversight of devices and recently a greater emphasis on the human–machine interface (http://www.fda.gov/MedicalDevices/DeviceRegulationsandGuidance/default.htm. Accessed July 22, 2011).

ELECTRONIC MEDIAL RECORDS, COMPUTERIZED PHYSICIAN ORDER ENTRY (CPOE), AND BAR CODE MEDICATION ADMINISTRATION

The value of electronic medial record (EMR) systems and particularly CPOE in preventing some types of medical error is obvious and was identified as a critical component of the roadmap for change in essentially all early publications on the topic of patient safety (49,50). As of 2011, there can be no doubt that EMR systems will be universal by the end of the decade. Unfortunately, despite initial promise and high expectations, these systems have also been found to promote new types of error (51–55). Similar to the observations in other medical devices, most threats arise not from the function of the system, but rather are due to insufficient attention paid to the human–system interaction characteristics of the design. Systems that work well in laboratory settings often fail when used in high-stress, high-stakes settings common in hospitals (55). The opportunity for safety-driven improvement is obvious, and it is the opinion of many that this improvement must be based on formal investigations into cognitive work in complex environments.

One strategy is to study work-arounds, a strategy utilized by Koppel et al. (56) in their study of BCMA implementation published in 2008. Like many other novel technologic advances, postimplementation examination of the technology is frequently associated with surprises. In a classic cognitive engineering text, Woods and Hollnagel (15) emphasize the need to assure that technology is designed to be a team player, with characteristics similar to those of effective human team players, such as transparency and predictability.

COMPUTERIZED DECISION SUPPORT

Decision support for the practitioner is widely considered to be the most valuable potential benefit of EMR systems (57). Human memory is limited, and the design of systems to compensate for human limitations is a critical component of human performance. Don Norman famously quipped that *"the power of the unaided mind is overrated…. (its) real powers come from devising external aids that enhance its cognitive abilities"* (58). The need to design these systems in a way that matches human performance is challenging—and to date most systems fall short of the promise (59,60). The promise is perhaps best illustrated by the title of the definitive text by Robert Greenes *"…the road ahead"* (61). Most EMR systems in use today have some level of decision support integrated into the CPOE component, although none are error-free. The most common form is through view alerts, in which a trigger "pops up" when a potentially unsafe medication (such as ordering an ACEI for a patient with known prior ACEI-related angioedema) is ordered (60). Unfortunately, most systems are "tuned" to eliminate all risk for the institution or EMR vendor, resulting in a plethora of view alerts, most of which are disregarded. Recent studies demonstrate that 90% of view alerts, including a substantial number of critical alerts, are routinely disregarded by physicians (62). It is obvious that much more needs to be done.

SIMULATION IN TRAINING AND ASSESSMENT

Simulation has been an integral component of aviation since WWII. Faced with the need to train thousands of pilots rapidly, the US Army Air Corps realized early that they would quickly run out of airplanes—and pilots—if they did not identify alternative training strategies. One of these was the development of the Link Trainer in which the novice pilot could develop the motor skills that would later function instinctively. The author recently encountered a commercial airline pilot who related the following story confirming the value of simulation training:

"Two weeks ago I lost an engine on take-off. Although the aircraft will fly if it has reached adequate speed for lift-off, there are several procedures which the pilot must do quickly to assure it continues to fly. Losing an engine on take-off is a rare event, and one which most pilots never experience throughout their entire career. However, we practice it—and are tested on it—in every routine training session in the simulator. Two weeks ago was my turn to be tested, this time with a full airplane.

Just as we left the ground I heard the sound, saw the data, and immediately knew what had happened. I and my co-pilot quickly did the correct procedures, just as we had practiced over and over, and the plane responded just as in the simulator. After several minutes when the situation was stable I keyed the intercom to tell the passengers that we had lost an engine and were circling in order to dump fuel (an airplane is too heavy to land with full fuel tanks). As I keyed off the intercom after I had informed them it struck me. My voice wasn't shaking. It was just as I had done in the simulator. Throughout the entire event I had calmly done the correct procedures in the correct order. Our training in the simulator may well have prevented a catastrophe."

Simulation in aviation is now utilized not only for training, and for rehearsal of rare events, but also for certification. In a similar manner, simulation training is becoming ever more utilized as a safety intervention in training health care workers. Many surgical skills such as otologic procedures have been taught in the laboratory for many years, and with the introduction of new simulator technology, it seems inevitable that much learning now done in the OR will occur instead in the simulator laboratory (63,64). In some specialties, "high-stakes" simulation testing is utilized for certification, and there are early investigations into its use in otolaryngology (65). It can be assumed that simulation of all types will represent an ever-increasing role in training and assessment in future years.

PHYSICIAN FATIGUE AND WORK HOURS

The expectation that physicians must work long hours in their training in order to develop the knowledge, skills, and attitudes necessary to provide safe and effective patient care was standard in the United States until early in the 21st century. The death of Libby Zion in 1984 is widely assumed to represent the "beginning of the end" for unlimited work hours for residents. Over the intervening quarter of a century, multiple changes in work regulations have been introduced, many introduced following the 2008 IOM report (available at http://www.IOM.edu/reports/2008/Resident-Duty-Hours-enhancing-sleep-supervision-and-safety.aspx. Accessed July 22, 2011), which reviewed the evidence for fatigue as a patient (and resident) safety issue and made multiple recommendations. The issue is still in flux in 2011 and is likely to be so through the entire life expectancy of this edition. Sexton surveyed surgeons and pilots and noted that although pilots were well aware of the effects of fatigue on their performance, physicians were more likely to believe that fatigue did not affect their performance (66). One factor limiting the benefit of more rested physicians has been the requirement for more handoffs. The requirement for more structured handoffs (67) is currently generating a number of innovations, of which none have yet been demonstrated to be superior.

CHECKLISTS

Checklists have been part of aviation and other high-stakes industries for years but only recently have become standard in health care. Checklists derive from an understanding of the cognitive limitations of humans—that is, humans have limited memory resources, and these resources degrade even more in periods of stress. Peter Pronovost is well recognized for his work in promoting the use of checklists and has been featured in the lay press for his actions in this regard. His seminal paper in 2006 demonstrating dramatic reductions in the incidence of central line infections after introduction of a simple checklist is viewed as a landmark innovation for patient safety (68). The use of checklists in the OR to assure compliance with Surgical Care Improvement Project (SCIP) standards is now standard in many facilities to assure that perioperative antibiotic and deep venous thrombosis prophylaxis, as well as other interventions, are not inadvertently forgotten. It can be assumed that checklists will become more common in future years.

CREW RESOURCE MANAGEMENT AND MEDICAL TEAMS

Following several high-visibility accidents in the 1970s the aviation industry came to the realization that planes were crashing due to faulty teams rather than faulty aircraft. From this arose the concept of training teams to work as teams, utilizing all the human resources as well as the technologic resources, with set rules and procedures (9). This training was initially termed "cockpit resource management" and later expanded to include the entire crew, hence the term "crew resource management" or CRM. Since its introduction in the late 1970s and early 1980s, there have been few accidents that have occurred due to failure of the cockpit crew to work together. In the intervening period, there has been a substantial effort to introduce CRM into the medical arena, often specifically termed "medical team training." The range of activities and procedures that have been spawned by this paradigm shift has been dramatic, and includes a number of strategies, such as the handoff issue above, with which all physicians are now familiar. The underlying principle is that all members of a team have a stake in team integrity and performance and share the responsibility of the outcomes of its actions. Communication is key to team function, and not only must team members speak up, but effective teams also respond to comments, observations, and recommendations. Effective teams flatten, (but do not eliminate) the

hierarchy, by empowering anyone on the team to speak up if necessary. In a manner similar to aviation, standard communication protocols are established, such as the SBAR (situation, background, assessment, recommendation) format for handoffs. "Time out," read-back, CUS words ("I am Concerned," "I am Uncomfortable," "Stop and Step back"), and pre- and post-op briefings are extensions of the concept of teams.

A fundamental requirement of teams is the so-called "basic compact," in which each team member commits to support the ongoing integrity of the team. Teams facilitate coordination among their members. Team members are inter-predicable in that actions of members are predictable by others. Members bear a responsibility to correct faulty knowledge and to be sensitive to factors that degrade the compact. A study of team member perceptions by Makary et al. suggested that considerable disparity exists among team members' opinions of team functioning. Perhaps not surprisingly, surgeons consistently rated team effectiveness at a higher level than either anesthesiologists or nurses (69).

The VA embarked on a formal team training program that sought to train OR teams in all VA hospitals and determine the outcomes of the training. Comparing the VASQIP risk-adjusted mortality in the 74 institutions suggested a dose–response relationship (70). Although it is feasible that the decrease was due to other, possibly unrelated factors, nonetheless the study lends credence to the value of formal team training.

CONCLUSIONS

Patient safety remains a fundamental threat to all who either receive or administer health care. Despite multiple innovations and investment of countless resources, the challenges continue. The otolaryngologist must not become discouraged by the lack of progress but rather must participate in efforts to improve safety for all who are at risk.

HIGHLIGHTS

- Adverse effects of medical care are common, and the personal and fiscal costs impact patients and their families, health care workers, and society. Many adverse effects are due to medical errors, which are estimated to cause the deaths of one in twenty Americans.
- An understanding of human performance and the causes of human error informs us regarding the causes of medical error. Health care workers strive to provide optimal care and do not knowingly put their patients at risk. The roots of most medical errors are due to flawed systems, not flawed individuals; hence fixing systems is a more effective strategy than "fixing" individuals.
- The ultimate goal of patient safety is to protect patients. Since human error cannot be eliminated, strategies to protect the patient from the effects of error are more effective than trying to prevent error. Defenses vary in permeability. Some are more protective than others. "Forcing functions" are more effective strategies than advising health care workers to "be careful."
- Study of the aviation industry can suggest strategies to improve safety within the health care industry, particularly no-fault reporting, simulation and team training, and rapid dissemination of lessons learned.
- Reporting, collating, and studying adverse events and near misses can inform system design to reduce the likelihood of patient injury due to human error.
- Health care workers are not relieved of personal responsibility for patient safety. A just culture seeks to define the balance between system responsibility and individual responsibility.
- Human cognitive performance is affected by fatigue, distraction, and stress. "Time out" and checklists are strategies to compensate for imperfect human performance.
- Most health care today is delivered by teams, not individuals. High-performance teams are safer than high-performance individuals. Teams vary in their effectiveness, and team function is measurable.
- Responding to errors requires attention to the needs of both the patient and health care worker. Honest disclosure and apology are effective in maintaining a healthy ongoing relationship that is healing for both patient and physician.
- Root cause analysis and other tools can be useful in dissecting the causes of adverse events, identifying the causes of error, and informing system design to reduce recurrence of such events.

199 Business Law and the Practice of Otolaryngology

Robert S. Iwrey *Stephanie P. Ottenwess* *Jessica L. Gustafson*
Kathryn Hickner-Cruz *David M. Ottenwess* *Reginald Baugh*

With the continuing avalanche of new regulations, the ever-tightening belt of third party payor reimbursement, the increased scrutiny by federal and state enforcement authorities, the increased emphasis on cost-containment and pay-for-performance measures, and the always looming threat of medical malpractice actions, physicians find themselves having to play the role of accountant, attorney, billing consultant, business manager, financial advisor, risk manager, and, if time permits, practicing physician. Long past are the days when a physician could simply devote virtually all of his or her professional time seeing patients and providing high-quality care.

In today's environment, physicians must still focus on providing high-quality care to their patients; however, they may also need to delegate certain aspects of the business side of medicine to the right individuals in order to optimize their success. This may seem counterintuitive to some in that in order to maintain control over their practice as a whole, physicians must learn to let go of some of the pieces.

The most important first step to gaining or regaining control over one's practice is to identify key advisors and specialists. Selecting an experienced health care attorney and an accountant with significant experience in representing physicians and physician practices is crucial as they can help navigate through the often murky waters of the health care regulatory landscape. There are numerous legal and accounting aspects of starting, maintaining, expanding, merging, and even closing a medical practice that require professional advisors to guide physicians so as to avoid the myriad of serious negative consequences that can result from noncompliance with the ever-changing rules of the game. Some of these consequences include, but are not limited to, overpayment demands by third party payors, departicipation or exclusion from third party payors, civil fines, and even criminal sanctions. Experienced, qualified health care attorneys, accountants, and other advisors can mitigate against the risks of facing such consequences as well as assist in crucial administrative matters for example, obtaining and maintaining the appropriate licenses (such as one's medical license, controlled substance license, drug control license, and Drug Enforcement Administration [DEA] registration), obtaining the best financing for medical and office equipment and supplies, obtaining the appropriate insurance (e.g., professional liability, personal liability, property, workers' compensation, directors and officers liability policies, and even policies now available to insure against fines and defense costs for billing errors and omissions).

Some physicians find it helpful to consult with a business advisor as well to sit down with the other professional advisors and to help develop a business plan based upon the physician's desires and needs. Such plans may include staffing determinations, changes in physical location, adding ancillaries such as imaging and laboratories, marketing, and developing affiliations with other health care providers, entities, and organizations. Prior to implementing such plans, it is a good idea to run them past one's key advisors to assure legal compliance.

Another important step is to make sure that the physician has a good understanding of where his or her practice stands in terms of the billing of professional services rendered. Remember, a physician alone is responsible for the use of his or her provider number. Whether one chooses to do his or her own billing, to employ an in-house biller, to contract with an outside company, or to rely upon his or her employer, ultimately the physician is responsible for the claims submitted under his or her provider number. Thus, if a physician chooses to rely upon others to do his or her billing, the physician should make sure that he or she has the requisite knowledge and experience in his or her specific field of practice. Being proactive, asking the right questions, and researching the prospective biller prior to engagement are time well spent and can save the physician significant headaches in the future. While the enforcement authorities *may* find that the physician did not have the requisite intent for criminal prosecution because his

or her biller made the errors and not the physician, the physician will still incur significant costs in both time and money defending the billings, and very often, the physician is subject to significant fines and penalties on top of returning monies to which the physician believed he or she was entitled and upon which he or she relied in the operation of the practice. As such, the physician needs to be familiar with the billing rules as they pertain to his or her specific area of practice. Responsibility for this knowledge and expertise should not be delegated.

Of course, no chapter on the business of medicine would be complete without discussion of medical malpractice and the efforts to reform the system—which to many appears broken and sorely in need of repair but without a viable solution. For the past three decades, medical malpractice tort reform has remained a highly polarizing, heavily contested legal issue, which affects not only physicians and attorneys but also the great many Americans seeking health care each year. But why does this legislation inspire such fervency in those that revile it and in those that champion it? Ask its critics, which typically include much of the plaintiffs' bar, and the answer is simple: medical malpractice tort reform strips individuals of their ability to redress injuries that they have incurred and right the perceived wrongs that have been committed against them. To its advocates, the answer is equally clear: medical malpractice tort reform is the mechanism by which defensive medicine is prevented, doctors' personal and professional livelihoods are protected, and litigious plaintiffs with frivolous lawsuits are deterred from bringing suit. While both sides make frequently valid and often convincing arguments, the reality of medical malpractice tort reform lies somewhere in the middle. It is a legislatively constructed concept, which has made its impact, both positive and negative, on the American legal landscape.

The purpose of this chapter is to provide the physician with a general overview of some, but not all, topics of interest to otolaryngologists regarding the business of medicine. It is by no means an exhaustive list as health care is a broad field and highly regulated with ever-changing laws, regulations, rules, advisory opinions, guidance, and contractual provisions. The goal of this chapter is to provide the physician with a business perspective of medicine and to arm the physician with enough insight and business savvy to recognize certain risk areas so that the physician may timely seek appropriate assistance in compliance with such areas and avoid the negative consequences often associated with a lack of knowledge.

MEDICAL LIABILITY

Medical Liability Claims in the United States

Introduction

Medical malpractice, or negligence law, is just one subset of the legal behemoth that is tort law. A tort is generally defined as a civil wrong that causes an injury, for which a victim may seek damages, typically in the form of money damages, against the alleged wrongdoer (1). Tort law is that body of law that serves as the vehicle by which tort liability can be sought in a court of law against such wrongdoers and generally serves to award damages to a victim sufficient to restore him to the position he would have been in, had the tortious conduct not occurred (1). Tort law typically governs three types of causes of action or, more simply phrased, legal theories of a lawsuit: negligence, strict liability, and intentional torts. A claim for negligence is brought when an injury results from an individual's failure to exercise the standard of care of a reasonably prudent person would have exercised in a similar situation (2). These matters involve unintentional acts that may cause harm. Actions for medical malpractice are classified under the umbrella of negligence claims. Claims for strict liability do not require an intent to harm or the presence of actual negligence but rather are based on the breach of an absolute duty to make something safe (3). Strict liability typically arises in situations that are considered inherently dangerous. For example, an individual who keeps a domesticated Siberian tiger in his home is strictly liable for any injuries that the tiger may cause, no matter the precautions the individual takes in protecting the safety of others. He need not be found to have breached the standard of care to be found strictly liable in such scenarios. Finally, intentional torts are defined as torts committed by a wrongdoer acting with intent (4). Examples of intentional torts include assault and battery, defamation, and false imprisonment.

Historic Analysis of Tort Law and the Evolution of Medical Malpractice Action in the United States

The modern system of American tort law and its district categories are by no means a recent construct. Tort law has existed in some form for hundreds of years, originating from English common law. Common law is defined as law that is issued from judicial decisions and not derived from legislatively enacted laws or statutes. Consequently, centuries-old decisions made by judges in England have greatly affected how the US legal system addresses actions for negligence, strict liability, and intentional tort. Taken one step further, the law that is applied in the most complex medical malpractice case can trace its ancestry to an English judge deciding whether a Welsh farmer's horse was negligently corralled during the 15th century.

The element of damages in tort law is of major significance and is integral to understanding the overall concept of medical malpractice law, mainly because the "runaway juries" have been the subject of great media attention and scrutiny. In tort law, compensatory money damages can be sought by a victim for both economic and noneconomic losses (5). Economic damages seek to compensate an individual for quantifiable economic losses, such as lost income and medical bills, while noneconomic damages are more speculative and seek to compensate an individual for noneconomic losses, such as mental distress and pain and

suffering (5). In certain rare scenarios, generally involving egregiously reckless conduct or behavior, a victim may also seek punitive damages against a wrongdoer (6).

Tort law is a function of state law, with each state providing different rules for bringing about a tort claim.[1] Procedurally, various states may approach tort claims differently; however, the basic premise of a tort claim and the elements that a plaintiff must prove in order to bring a successful cause of action remain consistent across all 50 states. This chapter focuses its state-specific discussion of tort law and medical malpractice tort reform on the state of Michigan and utilizes Michigan's experience with medical malpractice tort reform to illustrate how, in recent years, many states have attempted to handle the rising number of suits for medical malpractice.

The modern medical malpractice system in this country dates its origins to the 1840s, when the United States experienced a sudden surge in the number of medical malpractice actions brought in state courts (7). This boom could be attributed to the lack of a national "standard of care" for medical treatment, which often left patients seeking care from unqualified or unskilled medical practitioners (7). As the number of medical malpractice actions spiked, plaintiffs' attorneys also found a new niche in which lucrative careers could be made, primarily due to the availability of contingency fees, wherein a plaintiff's attorney receives as his fee one-third of the plaintiff's overall jury award or settlement. This time frame is typically considered the first medical malpractice "crisis," and the commencement of the long and complicated interplay between the medical community and the legal system.

The second significant medical malpractice crisis in the United States occurred in the 1970s and 1980s (7). During this time period, there was a rapid rise in the number of medical malpractice claims filed, as well as the size of awards made in medical malpractice actions. It has been estimated by the American Medical Association (AMA) that in 1975 as many as 14,000 malpractice suits were filed against physicians. The average jury award in these suits was $171,000 (7). The influx of medical malpractice claims and their subsequent jury awards created a chain reaction that had a far-reaching effect. Many private insurance companies began withdrawing from providing insurance coverage, and the insurers that remained responded by raising malpractice premiums. In 1975, it was documented that malpractice premiums had increased from anywhere from 100% to 750% (7). The sudden increase in insurance premiums, coupled with the loss of many private insurance companies from the market, resulted in some physicians leaving particular practice areas, or retiring from the practice of medicine altogether. It was the culmination of these factors that sparked a call for policy change at both the state and federal levels, and with that, modern medical malpractice tort reform was born.

Before addressing tort "reform" and its impact on the physician's practice, it is important to understand the anatomy of a modern medical malpractice case, as oftentimes the physician is quick to equate "reform" with the altogether elimination of medical malpractice claims from the American legal system. It is not the legal system, however, that is broken. Our civil litigation system has existed for centuries; it is only because it is so interwoven with and dependent on the human element that we see it as controversial. Consequently, a description of a malpractice action is in order that will outline the "theory" of litigation along with the "reality" of being a party defendant in a medical malpractice case.

Medical Malpractice Litigation

Anatomy of a Medical Malpractice Case[2]

General Legal Background

As a practicing physician with a highly advanced degree, years of sophisticated training, and a hard-earned professional license to protect, it is important to gain an understanding of the basic elements of a medical malpractice claim and the procedural aspects of bringing a lawsuit in order to best understand how to limit your exposure to claims of medical negligence. In today's legal environment, physicians often think that a lawsuit is a natural consequence of any "bad result" arising out of care provided to a patient. While a bad result should put the physician on alert that a suit may be on its way, a bad result does not, in and of itself, qualify as a legitimate malpractice claim. To bring, and sustain, an action for medical malpractice, the plaintiff bears the burden of establishing the four basic elements required of any negligence claim, with some variations. Specifically, the plaintiff must establish (a) that a physician or health care provider owed the plaintiff a duty of care, (b) that this duty of care was breached by conduct that was not in accordance with the standard of care that a reasonable physician would have employed under like circumstances, (c) that this breach was a cause of the plaintiff's injury, and (d) that the plaintiff suffered damages as a result of this breach (8).

[1]While tort law is primarily a function of state law, there is a Federal Tort Claims Act ("FTCA"), enacted in 1948, that provides that a private individual may sue the United States in a federal district court for most torts committed by persons acting on behalf of the United States. The FTCA imposes some limitations upon actions brought under the Act, specifically that the action must be brought in federal, rather than state court, the matter must be heard in a bench trial, presided over by a judge, and that the United States is not liable for any punitive damages sought by the plaintiff. In a medical malpractice context, claims brought pursuant to the FTCA most typically arise when an individual sues a VA or military hospital for medical negligence.

[2]Most of the authors' medical malpractice work arises out of claims filed in the State of Michigan. Consequently, examples and case law cited here will often involve specific Michigan rules and statutes.

In regard to the third element of causation, a physician's allegedly tortious conduct must be both the cause in fact and the proximate cause of the victim's injury. The cause in fact (or "but-for" cause) of a plaintiff's injury simply means that but for the physician's conduct, the injury would not have occurred. Proximate cause is a complex legal concept, one that is particularly vexing to first-year law students, but essentially, proximate cause can be defined as the initial conduct or act, which sets off a natural and continuous sequence of events that produces an injury.[3] In order for a plaintiff to successfully bring an action for medical malpractice, he or she must establish that the defendant's actions were both the cause in fact and the proximate cause of his or her injuries. Thus, because a bad result may be a natural consequence of treatment, there is no viable claim until a similarly situated physician testifies that the defendant physician breached the standard of care *and* that the breach was a cause of plaintiff's injuries.

Presuit

In a vacuum, a patient who suspects that he or she has been the victim of medical malpractice will retain an attorney who will determine if the plaintiff has a viable claim. If the attorney believes there is evidence of a physician's negligence, the attorney will conduct an investigation, which requires having a qualified physician look at the medical records involved and offer an opinion whether proper treatment was rendered in the case in question. Once the attorney is convinced that the expert will testify adequately about the legal requirements of duty, standard of care, and proximate cause, the attorney may initiate a lawsuit by filing a complaint, almost always in state court. But, in some instances, there may be ways to avoid a lawsuit and circumvent the entire adversarial litigation process.

As a practical matter, a patient who may feel that he or she received inadequate medical treatment due to negligence knows little or nothing about the "burden of proof" or what other legal requirements are necessary to proceed in a court of law. Consequently, a patient who has a negative experience is angry and wishes some redress or, if nothing else, a bit of an explanation as to why *he* fell into that small percentage of patients that his physician quoted as being at risk of a potential complication from the medical treatment in question. As a result, a patient really may only be looking for answers, rather than an attorney.

It is during this period that, in some instances, a physician can head off a lawsuit if her office is receptive to the patient's concerns. Some physicians have gone to great lengths to avoid speaking directly to patients about the "mechanics" of medicine when a less than optimal result has occurred. However, avoidance or vagueness almost always instills suspicion and can, by itself, be the impetus for a patient to head to the nearest attorney's office. One course of action to follow is to be as straightforward and direct with the unhappy patient as possible and to speak with them at length about their complaints if they seek out an explanation. Also, a physician should provide a patient with any requested medical records and may offer to refer a patient to another physician, if the patient so desires. While it is not in the physician's best interest to admit that anything he or she did was inappropriate (unless, of course, what he or she did *was* inappropriate, and then you must let your conscience be your guide), being empathetic to the patient's plight may even go so far as to head off a potential lawsuit.

Suit Filed: Discovery

Assuming that the patient is neither placated nor interested in an informal discussion about the patient's medical care and an attorney is retained who has obtained a positive review from an expert, the formal action is begun in court by filing a pleading known as a complaint.[4] The complaint initiates a civil action and outlines with specificity the basis for the plaintiff's medical malpractice claim and the relief that the plaintiff seeks (9). The complaint is then filed upon the opposing side, who in response must file an answer, which is the defendant's first pleading that addresses the merits of the case and generally denies the plaintiff's allegations and sets forth any of the defendant's defenses and counterclaims (10).

After the complaint and answer have been filed, the pretrial process of gathering evidence to support either party's position, referred to as the discovery stage of the proceedings, begins. During discovery, interrogatories are exchanged between the parties, which are written sets of questions that are required to be answered candidly. Also during the discovery period, depositions of the relevant witnesses are taken. A deposition is a witness' out-of-court testimony, which is taken under oath and recorded for later use at trial or to further additional discovery (11). Depositions are a critical part of the discovery process, as they assist counsel for both parties to focus their discovery requests and identify important issues to be addressed at trial.

The discovery phase of the lawsuit is really the nuts and bolts of the litigation process. The physician learns exactly the nature of the charges being advanced by the patient and what steps will be necessary to defend against the claims. In Michigan, the defendant physician will get some early

[3]Proximate cause "normally involves examining the foreseeability of consequences, and whether a defendant should be held legally responsible for such consequences." *Skinner v Square D Co*, 445 Mich 153, 163 (1994).

[4]In some states, such as Michigan, a Notice of Intent to File Claim (NOI) must be served before a formal complaint may be filed with the Court. An NOI puts potential defendants on notice that a case ***may*** be filed. By law, a claimant must wait approximately 6 months after serving the NOI before proceeding to a court action by filing a legal complaint.

inkling of the specific claims of malpractice being brought, as the plaintiff must file an affidavit of merit with the complaint. This affidavit must be executed by a similarly trained and certified physician who is prepared to testify as an "expert" witness that the defendant physician committed professional negligence. The entire scope of the expert's opinions, however, does not materialize until the witness is actually deposed. It is during the deposition of the expert that the attorneys are given, relatively speaking, free rein to delve into the bases of the expert's opinions and to examine the expert's background and training to verify whether the expert has adequate credentials and/or the adequate background to testify in the case.

Before depositions of experts can be completed, the defendant physician must undergo his or her own deposition. Short of trial, this is typically the most difficult part of the litigation process for a physician. A physician must be very well prepared for his or her deposition testimony, as such testimony usually only can "lose" a case and rarely ever results in one getting dismissed. It is therefore imperative that the pertinent medical records are reviewed in great detail prior to the physician's deposition and that the physician meet with the attorney well in advance of the deposition to ensure a comfort level for both the physician and the attorney. With the expense involved in litigating medical malpractice actions, the defendant physician can fully expect the plaintiff's attorney to be well prepared for the deposition, which makes it crucial that the physician not take the procedure lightly. While the actual process one must undertake to get ready for a deposition could fill another chapter, suffice it to say, the more prepared one is for grueling questioning, the better off the defense of the case will be. Remember, the plaintiff's attorney is not only listening to your every answer; she is also sizing you up to determine just how well you will present before a jury and exactly how you will handle yourself under difficult circumstances.

Having survived the deposition process, it may appear that your case has suddenly disappeared; do not be misled. The lull in the action is only due to the fact that your attorneys are now turning their sights toward taking the discovery of either other defendants or the plaintiff's expert witnesses. This process can usually take several months and only makes it *appear* as if nothing is moving.

Expert Witnesses

In a medical malpractice action in Michigan, as is true in virtually every state, the plaintiff *must* secure medical expert testimony in order to advance the case before a jury.[5] That is to say, before a jury can actually decide the merits of the case, the plaintiff must present expert testimony that the defendant physician breached the standard of care during the treatment of the patient and that that breach was a cause of injury to the plaintiff. This testimony is required because the typical jury does not, as a whole, have the requisite knowledge to decide intricate questions of medical treatment without the assistance of a qualified expert witness. Just what constitutes a qualified expert witness is a matter of discretion for the trial judge and is one of the "human elements" that make litigating a case more difficult. For instance, the judge may have a more liberal interpretation of what the expert needs to be "qualified," which can be frustrating to the defendant.

Because there are no standard rules regarding what is "proper" expert testimony, the use of expert witnesses in medical malpractice cases has become a main source of contention for many advocates of medical malpractice tort reform. As filings of medical malpractice lawsuits have increased throughout the country, the provision of expert witness testimony has become very lucrative for physicians across all medical disciplines. As a result, proponents of tort reform argue that because of the ease at which an expert can be retained to offer expert testimony on a medical malpractice claim, it is increasingly easier for plaintiffs to bring such claims, exacerbating the medical malpractice crisis in the United States. Thus, while theoretically the parties should get well-trained, credible, and reliable experts to testify, this is not always the case.

As a practical matter, proposed expert witnesses are not always bound by their ethical and moral obligations. Because the standard of care is, in most circumstances, neither codified nor objective in nature, there may be wide disagreement as to what really constitutes the "standard of care."[6] For the most part, experts, while genuine in their opinions, will oftentimes confuse their own practice, or what they believe the practice should be, with a national standard of care. For instance, while it is inappropriate for a physician in Michigan to testify about the standard of care in relation to what he or she does or does not do in their practice personally, many experts do just that. Because it is difficult to verify oft-stated, sweeping generalizations made by an expert that their opinions "are common knowledge," "may be heard at any meeting," or "can be readily found in the literature," the defendant physician may risk that a jury will simply accept unsupported statements as true because they do not possess the requisite knowledge of the subject matter. While steps can be taken to hold an expert's feet to the fire on certain medical issues, a liberal judge or

[5]In most states, the defendant physician is not necessarily *required* to secure an independent expert to testify on her behalf at trial as the defendant physician is considered an expert in her own right. As a practical matter, however, defense counsel almost always retains an independent, similarly situated physician to assist in the defense of the claim.

[6]In Michigan, the standard of care is defined as what an ordinary board certified physician would do or not do under like or similar circumstances. *Patelczyk v Olson*, 95 Mich App 281, 283; 289 NW2d 910 (1980).

sympathetic jury may be persuaded by an expert who does little else but sit in an office and testify against physicians.

Indeed, there are a few physicians who rely heavily on the income derived from testifying against physicians. It is highly lucrative, and the physician is at little risk for repercussions. Experts on behalf of the plaintiff will typically testify against physicians outside of their state, which gives them a comfort level that they would not ordinarily enjoy if they were testifying against a local colleague.

Progress has been made to limit and correct some of these problems. Various medical organizations have established their own ethical guidelines for expert witness conduct. For example, the American Academy of Otolaryngology–Head and Neck Surgery sets forth that an expert witness to a medical malpractice action should not adopt a position as an advocate or partisan in the legal proceedings; should review all the appropriate medical information in the case and testify to its content fairly, truthfully, and objectively; should review and be thoroughly familiar with the relevant standards of practice and medical literature prevailing at the time of the occurrence and limit their testimony to their areas of expertise; should be prepared to state the basis of the testimony presented and whether it is based on personal experience, specific clinical references, or a generally accepted opinion in the specialty field; should be compensated at a rate that is reasonable and commensurate with the time and effort given in preparation for testifying and should not link their compensation to the outcome of the case; and should be aware that transcripts of their deposition and courtroom testimony are public records, subject to independent peer review (12).

Stringent ethical guidelines, such as the ones imposed by the American Academy of Otolaryngology–Head and Neck Surgery, help ensure that expert witness testimony offered in medical malpractice actions is scientifically truthful and founded in reliable and universally recognized methodologies. These guidelines protect the equitable nature of the civil litigation process and hold accountable expert witnesses who proffer less than truthful medical opinions under oath.

While individual societies are trying to take steps to reign in unreliable testimony, it is not likely to vanish entirely. What constitutes the standard of care is simply too subjective in many instances, and the lines of what constitutes an exercise of judgment and what constitutes medical negligence are often blurred. The important thing to note is that the defendant physician should try to avoid taking any such criticisms personally and should consider the source of those opinions when applicable.

The End Game: Settle or Not to Settle

Once discovery has been completed in a particular case, counsel will begin the process of a cost–benefit analysis of whether a case should, or even can, proceed to trial. This is usually the most difficult part of the case for the defendant physician. The defendant is faced with a Hobson's choice of either grinding it out in trial, with no guarantee of success, or suffer the ignominy of "caving in" to the plaintiff's demands. While those views represent opposite ends of the emotional continuum, the defendant physician experiences these pangs of emotion when deciding what to do.

Before the physician arrives at a decision about settlement versus trial, counsel must first do a complete analysis of the case to determine whether from a factual and legal standpoint, there is a good chance of prevailing at trial. To that end, counsel will analyze all of the opinions of the defendant physicians, the subsequent treating physicians, and the expert witnesses. Counsel will take into account the jurisdiction (where the case is located), the judge involved in the matter, the attorney who is representing the plaintiff, and, perhaps most importantly, the presentation of the client himself. While having excellent experts and a great judge on a case is extraordinarily helpful, those factors may pale in the face of a tentative witness, who also happens to be the defendant. Juries often look to the parties, that is, the plaintiff and the defendant physicians, in order to formulate a decision about the case as, oftentimes, they have heard polar opposite testimony from the experts on the question of whether the defendant breached the standard of care. So, while a case may be extraordinarily "defensible," it may be impossible to move forward with trial because of the personality or fortitude of the defendant physician.

Similarly, many physicians simply cannot afford to be out of the office for several days or several weeks while a trial is being conducted. Trials are typically a session of consecutive days until completion and often take all day to attend. It is easy to "fight to the death" on a case when your physical presence is not needed leading up to trial and your own time and assets are not at risk because your insurance dollars are paying all of the discovery costs and expenses. But when trial is imminent, hard decisions need to be made. It is only when the defendant traverses the "courthouse steps" that either backbones stiffen or knees buckle. Consequently, settlements may be made strictly from a convenience or emotional standpoint, as opposed to on the merits of a case.

Another major reason why cases typically will not proceed to trial is that the defendant physician simply cannot stand the process emotionally. Indeed, it is very difficult to sit through days, if not weeks, watching a parade of witnesses criticizing your every action. Further, the inability to understand the procedural machinations of the court can sometimes make matters extraordinarily frustrating. As a result, it is the rare physician who will take that trip to trial on more than one occasion.

Once it is determined that you want to move forward with trial, new anxieties arise. The question of "How can a jury of lay people possibly understand the medicine and decide in my favor?" is a common concern. Indeed, this fear is often the major reason to settle a case. It is here that counsel must ensure that the issues presented in the case are concise, relevant, and put into language that the jury

can understand. For the most part, juries can be trusted to understand the issues presented in a medical malpractice action and with the proper preparation on the part of defense counsel, a jury will typically make an informed decision.

If a defendant physician does in fact decide to go to trial, he must be prepared to enter an entirely different world and face a process that can be potentially grueling and involves going to court on consecutive days until the case is complete. One of the first steps of trial that a physician will witness is jury selection. Initially, a group of individuals, called the veneer, are brought into the courtroom and prospective jurors are selected randomly to hear the case. Before the jury is sworn in, the attorneys and the judge will ask questions to determine whether any of the potential jurors have any biases or prejudices that would render them incapable of arriving at a fair verdict. This process is known as voir dire. Once the jury is impaneled, the parties proceed to opening statements and then evidence is produced, hopefully, in a reasonable fashion. Once all of the evidence has been heard, both sides have rested, and plaintiff has met his burden of proof to present a *prima facie* case of negligence, the jury is charged by the court to decide the case. The jury then deliberates in private and renders a verdict.

This brief overview of the trial process encapsulates what can amount of many weeks worth of events and also is based on the assumption that all the parties involved in the process will be reasonable. More often than not, that is not the case, as in the adversarial setting of a courtroom it is the opponent's job to be unreasonable. Furthermore, some judges, possessing little more than a rudimentary understanding of the medical issues involved, sit and decide important evidentiary issues. Fortunately, the jury decides "guilt" or "innocent"; however, this may provide little comfort to the physician in the hot seat.

As if 2 years of litigation culminating in a long drawn-out trial were not enough, if the physician prevails, the plaintiff has the option to appeal. Depending on the state in which the case sits, the appellate process may take another additional 1 to 4 years. After sweating it out for this period, the appellate court could overturn your hard-fought win and require you to relitigate your case. Thus, given the many unknowns that are associated with trial, physicians and their insurance carriers will look closely at each of the factors involved with a case to determine the best course.

On the other hand, the consequences of settling the case are a bit clearer. First, the case has ended completely with no chance of it hanging over the defendant's head *ad infinitum*. A release and settlement agreement is entered into, which, in some cases, allows for a confidentiality agreement; that is, the terms of the case cannot be discussed by any of the parties. Also, the physician is not admitting negligence by entering into a settlement agreement, only resolving a "disputed" claim. The only real cost with this course of action is a mandatory report to the National Practitioner Data Bank and perhaps a wounded ego. While this is not necessarily desirable, settlement at least allows the physician to move forward without protracted litigation hanging over her head.

Medical Malpractice Insurance

Because of the risks associated with litigation noted above, along with the sheer number of malpractice claims filed annually in the United States, it is not surprising that professional liability insurance has, and should, become a high priority for most practicing physicians and health care professionals. Professional liability insurance can serve a number of goals, the most important of which is the protection of a physician's personal and professional assets and the provision of legal support if a lawsuit is initiated. While most states legally require a physician to purchase a minimum amount of professional liability insurance, there are various other components to consider when deciding what type of coverage best fits a physician's specific needs.

Certain elements affect how much professional liability insurance a physician requires, including the physician's practice area, whether his state requires a minimum level of coverage and whether the physician is willing to jeopardize his personal assets if his level of coverage is insufficient. Once it has been determined exactly what a physician's unique needs are, it is then important to evaluate potential professional liability insurance carriers based upon the levels of protection that they offer against lawsuits, their financial solvency, their process for handling specific medical malpractice claims, and the type of coverage they offer.

Professional liability insurance carriers often offer one of two types of coverage: an occurrence policy or a claims-made policy. An occurrence policy offers protection from losses, which occurred while the policy was in effect, or during the policy term. Furthermore, an occurrence policy will continue to cover those losses any number of years in the future, even if the policy has since expired. For example, if a physician buys an occurrence policy in 1999 and terminates the policy in 2009, he will be covered for any incident of alleged malpractice that occurred in that period of 10 years, even if he is sued for such an incident in 2012, well after the occurrence policy has expired. Essentially, with an occurrence policy, a physician is covered for any incident that occurred during his or her policy term, no matter when he or she is sued. Occurrence policies are especially attractive to physicians because often evidence of alleged medical malpractice is not discovered until many years in the future and occurrence policies allow physicians to remain protected from any potential undetected exposure. Occurrence policies are, however, typically more expensive than a traditional claims-made policy, due to their permanence.

A claims-made policy is also another viable option for professional liability insurance coverage. Claims-made policies differ from occurrence policies in that they offer protection from claims made during a specific time period. A claims-made policy must continually be renewed from the time of the alleged incident to the time the claim is

filed, and when a claims-made policy expires, a physician no longer has coverage in the future for alleged incidents of malpractice that occurred in the past. For example, if a physician purchases a claims-made policy in 1999 and renews it until 2009, at which point the physician allows it to expire, the physician will not be covered from a potential claim that is brought in 2011, even if the alleged act of malpractice occurred in 2006, when he or she had claims-made coverage.

In order to reduce their risk of liability exposure, physicians with claims-made policies will often purchase what is called tail coverage. Tail coverage serves to cover losses that occur after a claims-made policy has expired. Functioning much like an occurrence policy, tail coverage protects a physician from claims made after the expiration of the claims-made policy, but which occurred while the policy was effective. For example, a physician purchases a claims-made policy in 2002, which he renews until 2004, at which point he allows it to expire. He then purchases a tail policy in 2004, which protects him from any claims brought against him during the 2002–2004 time frame during which the physician was insured.

The primary difference between tail coverage and an occurrence policy is that when an occurrence policy expires or is terminated, the physician is no longer required to pay premiums on the policy and yet, will continue to have coverage for any losses that occurred during his or her policy term. With tail coverage, the physician must continue to pay premiums until he or she no longer wishes to have protection from incidents that may have occurred during the time the physician's claims-made policy was in effect.

The decision whether to purchase claims-made or tail insurance is a complicated one, which should take into account your particular needs and exposure risks. Claims-made policies offer physicians great flexibility because they are renewed annually, allowing an individual to revise or change his insurance coverage. Furthermore, claims-made policies are portable and may be transferred between insurance carriers, while occurrence policies remain with their original carriers, as they are permanent. Occurrence policies, however, are not without their advantages. An occurrence policy offers protection *ad infinitum*, is not required to be renewed, and does not require the additional purchase of supplemental or tail coverage.

Finally, it is important to consider that in the context of medical malpractice professional liability insurance, a physician's insurance premiums may be covered by the hospital or practice group that employs him. Typically, in such instances, this coverage is made on a claims-made basis. Therefore, if the physician is then to leave the hospital or practice group for other employment, it is critical that he purchases tail coverage to protect against any potential liability that may have occurred while working for his former employer.

No matter the type of insurance coverage a physician chooses to purchase, a physician's protection of his personal assets must be a top priority, particularly in light of the fact that a physician may be personally liable for any portion of a judgment or settlement in excess of his professional liability insurance coverage. After the lengthy and expensive process of obtaining a medical license, a physician must utilize every asset protection strategy available to him to protect his livelihood, including sound tax and estate planning and low-risk financial investments.

Asset protection strategies can be easily implemented by a physician with little expenditure of time or effort. For example, a physician can maximize his contributions to his IRA or other qualified employee benefit plan, which are typically shielded from claims of creditors. Various life insurance arrangements may also be considered, as many jurisdictions exempt all or part of the cash value of a life insurance policy from creditor claims. It is also critical to hire an experienced estate planner, who can suggest trust arrangements that offer significant asset protection and may provide some protection from the claims of creditors, and a knowledgeable accountant or tax expert, who will suggest methods by which to protect assets from various taxing authorities.

While maintaining insurance to protect personal assets is the overreaching goal to the insured, there are other avenues of insurance coverage, which, if appropriately managed, provide security and could ultimately produce income. Offshore captive insurance groups have become very popular with large health systems and large physician groups. Essentially, offshore captives are developed and owned off of the US borders by the insured parties. The captives are subject to the insurance laws of the country of domicile and are not formally required to adhere to US insurance regulations, like a typical domestic or US-domiciled company.

The upside for ownership interest in a captive is a potential return on your premium dollars. Instead of paying a local insurance company tens of thousands of dollars in premiums—money that will never be recouped—these insurance dollars may be placed in a captive, where theoretically, those dollars will grow, ultimately leading to distributions or, at least, a tangible asset. It is important to understand, however, that in order for these entities to become viable and, later, profitable, they must be well capitalized and very well managed—usually with outside underwriters, actuaries, and financial advisers. A well-run offshore captive can turn a liability, insurance premiums, into an asset.

On the other hand, an undercapitalized or poorly managed captive can be a physician's worst nightmare. Poor planning, reckless underwriting, or fraud can spell doom for the captive and could result in zero insurance protection to the participating physician for a period of time. Just to litigate a medical malpractice case up to the time of trial can cost upward of $200,000.00. This figure does not include trial costs, appeals, or a possible verdict, which can be staggeringly expensive. Stated simply, a lack of insurance could result in bankruptcy, humiliation, and a possible legal investigation.

The physician just beginning practice should ask many questions if his or her new group owns its own insurance

company and obtain counsel if necessary—as this could make the difference between entering into a practice with a viable, sound captive and entering into a practice with a poorly managed captive destined for failure and economic ruin.

Tort Reform

Theory

In response to the above-mentioned criticisms of medical malpractice litigation and the medical malpractice crisis of the 1970s and 1980s, physicians and malpractice insurance carriers began to lobby heavily for changes to reduce medical malpractice tort liability. Proponents of medical malpractice tort reform argued that as a result of changes to laws governing medical malpractice claims and their associated awards, malpractice insurance premiums would decrease. They further argued that lower insurance premiums for health care providers would increase the number of practicing physicians, lower the costs of health care for consumers, and result in an overall improvement in available medical care. These arguments obviously struck a chord in state legislatures throughout the country because by the mid-1980s, medical malpractice tort reforms had been widely adopted. It is important to note that while medical malpractice reform legislation was introduced at both the state and federal levels, as will be discussed below, attempts to pass real reform have taken hold on the state level, while attempts at passing federal legislation have been unsuccessful.

Typically, medical malpractice tort reform at the state level has focused on legislative reforms to the general doctrines of tort law, such as rules governing punitive damages, noneconomic damages, collateral sources, and joint and several liability (13). These doctrinal reforms have had varying degrees of success throughout the nation, with some reforms being widely adopted across all jurisdictions, and others being less enthusiastically received.

State laws capping noneconomic damages have been just one of the legislatively implicated medical malpractice tort reforms. Advocates of tort reform argue that noneconomic damages are arbitrary and unpredictable and, as such, complicate the settlement process. Further, it is argued that losses for emotional distress and pain and suffering are intangible and exceedingly difficult to assign a dollar value. Currently, over 30 states have caps on noneconomic damages as applied to medical malpractice actions.[7] These limitations on noneconomic damages vary across jurisdictions: some states employ caps on both economic and noneconomic damages in medical malpractice awards; some states apply noneconomic damage caps only to certain types of malpractice claims, such as obstetrics; and other states allow for increased recovery in particular scenarios, such as where the patient has died or has substantial physical injury (14).[8] Typically, the limit on noneconomic damages varies on a state by state basis, with caps on damages ranging from $250,000 to $500,000 (14).

The tort law concept of joint and several liability has also undergone significant tort reforms in the context of medical malpractice claims. Traditionally, joint and several liability allows a plaintiff, who has been injured by two or more wrongdoers, to recover the full amount of his damages from any one of the defendants that may have been involved in the tortious conduct. This has historically resulted in an injured party seeking damages against the defendant with the most financial resources. A party sued under a theory of joint and several liability may then seek contribution from the additional parties at fault, so that the other defendants have to share in the payment of damages. Oftentimes, however, contribution cannot be achieved because the additional at-fault parties lack the financial means to contribute. As a result, proponents of tort reform argue that joint and several liability is an inequitable concept because one defendant, generally the defendant with the most financial resources, is required to pay damages in an amount considerably more than his share of the total liability. This criticism has caused over 40 states to enact tort reforms to the joint and several liability system, either outright abolishing joint and several liability or requiring an individual defendant to pay an amount of damages proportionate to his share of the overall fault (15).[9]

States Where Tort Reform Has Been Enacted

Michigan serves as an illustrative example of how the specific states have addressed medical malpractice tort reform in an attempt to deal with the modern medical malpractice crisis. In recent years, Michigan has passed sweeping legislation curtailing frivolous litigation in the context of medical malpractice. For example, in 1986 the state passed a rule allowing a court to assess attorneys'

[7]States with noneconomic damages caps include Alabama, Alaska, California, Colorado, Florida, Georgia, Hawaii, Idaho, Illinois, Kansas, Maine, Maryland, Massachusetts, Michigan, Minnesota, Mississippi, Missouri, Montana, Nevada, New Hampshire, North Dakota, Ohio, Oklahoma, Oregon, South Carolina, South Dakota, Texas, Utah, Washington, West Virginia, and Wisconsin. [8]*Compare* Mont. Code Ann. § 25-9-411 (2005) (cap of $250,000), *with* N.D. Cent. Code § 32-42-02 (1996) (cap of $500,000).

[9]States with such reforms include Alaska, Arizona, Arkansas, California, Colorado, Connecticut, Florida, Georgia, Hawaii, Idaho, Illinois, Indiana, Iowa, Kansas, Kentucky, Louisiana, Massachusetts, Michigan, Minnesota, Mississippi, Missouri, Montana, Nebraska, Nevada, New Hampshire, New Jersey, New Mexico, New York, North Dakota, Ohio, Oklahoma, Oregon, Pennsylvania, Rhode Island, South Carolina, South Dakota, Tennessee, Texas, Utah, Vermont, Virginia, Washington, West Virginia, Wisconsin, and Wyoming. American Tort Reform Association, http://atra.org/issues/index.php?issue=7345 (Last visited Dec. 6, 2010).

fees and costs for filed actions that are perceived as frivolous (16). In 1993, Michigan also enacted noneconomic damages caps in medical malpractice actions, limiting the award of noneconomic damages in medical liability cases to $280,000 for ordinary occurrences and $500,000 in cases where the plaintiff has suffered serious damage to the brain, spinal cord, or reproductive organs (16). In 1995, the state passed a reform to the rule of joint and several liability, barring the application of joint and several liability in the recovery of all damages, except in cases of medical malpractice where the plaintiff is determined to have no allocation of fault (16). The Michigan state legislature additionally passed reforms to the collateral source rule in the context of medical malpractice litigation (16). Prior to passage, the collateral source rule prohibited the presentation of evidence at trial that an injured party has received compensation for his losses from another source, such as an insurance policy. The collateral source rule reform passed by the state of Michigan as part of the overall medical liability reform package now provides that medical malpractice awards be offset by the amount of collateral source payments received by the plaintiff (16).

Through the adoption of comprehensive medical malpractice tort reform, Michigan has done what many other states have wished to achieve: the near-total elimination of all medical malpractice litigation. Indeed, reform began to gain traction in Michigan in the early 2000s following a series of conservative holdings by the State's Supreme Court strictly interpreting the key medical malpractice reform statutory provisions. Reports from the State of Michigan Office of Financial and Insurance Regulation (OFIR) demonstrate that reported claims[10] for the period 2000–2007 show a 77% decrease in court filings (1,142 in 2000 to 263 in 2007). This is a significant drop in cases, which has resulted in a modest drop in insurance premiums. Nonetheless, as will be discussed in the "Compliance and Regulatory Issues" section of this article, health care costs have not declined. Contrary to assertions that less litigation will protect physicians from the constant threat of second-guessing from their patients who have obtained a less than optimal result, health care costs and unnecessary testing has continued to rise.[11]

Despite the adoption of the above-mentioned tort reform measures throughout a variety of US jurisdictions, tort reform has yet to gain momentum on a federal level. Attempts at passing federal legislation restricting medical malpractice liability have failed since the 1970s, when federal tort reform was proposed in response to the first modern medical malpractice crisis. While contemporary presidents and politicians have campaigned for the adoption of far-reaching federal tort reform, all have failed in their efforts. In 2004, President George W. Bush proposed tort reforms affecting the liability exposure of physicians and drug and medical equipment manufacturers; however, opposition in the U.S. Senate prevented the enactment of this federal legislation (17). Additional proposals made in 2005 sought to cap noneconomic damages in medical malpractice actions, restrict the availability of punitive damages, restrict the statute of limitations for medical malpractice suits, and limit contingency fees collected by plaintiffs' attorneys in jury awards (18). Again, this federal legislation failed to get out of Congress.

With efforts at federal tort reform legislation stalled, it is impossible to determine the effect federally implicated restrictions on medical malpractice liability would have on overall national health care costs. It is, therefore, critical to consider whether medical malpractice tort reform at the state level has achieved the movement's stated goal: to reduce health care expenditures.

Relationships between Medical Malpractice Litigation and Health Care Costs

Impact on Rising Health Care Costs

One of the greatest criticisms leveled at the medical malpractice tort system is that the defense of medical malpractice actions needlessly increases the costs of health care in the United States. Medical malpractice tort reform advocates have long argued that the ever-present threat of litigation forces health care providers to charge higher rates to offset the costs of rising malpractice insurance premiums as well as promotes the practice of defensive medicine, which is defined as the overuse of diagnostic testing and health services in order to minimize a physician's liability exposure. The contention that medical malpractice tort reform is the soundest means by which to stabilize malpractice insurance premiums and generally lower health care costs, however, remains a controversial stance among both the legal and medical communities.

Much of the research conducted on the medical liability system suggests that in actuality, costs surrounding medical malpractice litigation are a small fraction of overall health care spending in the United States. Per the National Association of Insurance Commissioners, the overall cost of defending medical malpractice claims and compensating victims of medical malpractice in 2007 was estimated at $7.1 billion, a mere 0.3% of the annual health care costs for that year (19). Even when these figures account for the

[10]State of Michigan Office of Financial and Insurance Regulation, Evaluation of the Michigan Medical Professional Liability Insurance Market (October 2009). Although the OFIR report includes only those entities that filed a "Form A" notice and does not include many filings against self-insured captives insuring many hospitals and physicians in Michigan, the study is still a good indication of the percentage decline throughout the entire state.

[11]Interestingly, although the American Medical Association and other physician organizations wanted substantive medical malpractice reform to avoid "defensive medicine," no such reforms were seriously considered in the recent health reform debate—a debate where rising health care costs was *the* impetus for the resultant enacted legislation.

use of defensive medicine, as well as the expense of defending medical malpractice claims and compensating plaintiffs, the total costs associated with medical malpractice litigation are modest relative to overall health care spending. In 2008, the annual medical malpractice tort system costs, which included the costs of defensive medicine, were estimated to be $55.6 billion, or 2.4% of the total health care costs for the year (20).

If recent statistics appear to reflect that the cost of medical malpractice litigation does not have an overwhelming effect on the overall cost of health care spending, then why have rising health care costs been routinely evoked to demand the adoption of medical malpractice tort reform? The answer may lie with the perception perpetuated by insurance and health care provider lobbyists alike: that the practice of defensive medicine, as well as increased malpractice insurance premiums, is the direct result of increased medical malpractice litigation. Empirical evidence has shown, however, that malpractice insurance premiums are much less affected by medical malpractice litigation than commonly believed and that the costs of defensive medicine are often exaggerated.

Insurance Premiums

During the previously mentioned cycles of medical malpractice crises in the United States, malpractice insurance premiums have generally risen dramatically. Advocates of medical malpractice tort reform point to these premium increases as evidence that medical malpractice claims drive the rising cost of health care. While there is no question that rising insurance premiums place an additional financial burden on physicians seeking malpractice coverage, premium rates are not based solely, or even in large part, upon medical malpractice claim or settlement payouts (21). This is because most insurance companies' profits are not generated from the premiums they receive from their insured physicians (21). Most malpractice insurance carriers face a delay between the time they receive premium payments from their insured physicians and the time they have to pay out medical malpractice claims. Due to this delay, many insurance companies invest the premiums they receive in bonds or other financial securities (21). It is the return on these investments, not malpractice insurance premiums, that generates an insurance company's profits. Therefore, even if the number of malpractice claim payouts an insurance company makes is stable, the company may still be forced to raise premiums if their investments fail to yield adequate returns (21).

In addition, premiums do not only represent a malpractice insurer's indemnification costs. Malpractice insurance premiums represent a variety of costs assumed by an insurance company and passed on to their insured physicians. These costs may include a company's estimated indemnification costs, defense costs, operating fees, reinsurance costs, and profit or surplus building (22). Tort reform opponents argue that even with legislature in place to limit jury awards or settlements in medical malpractice actions, rising insurance premiums would still be a financial hardship faced by the medical community, as the underwriting cycle and malpractice premiums are affected by much more than the threat of medical malpractice litigation.

Research performed in states that have enacted tort reform in the context of medical malpractice litigation also indicates that rising malpractice premiums are not tied to an influx of medical malpractice filings. In 1986, the state of Florida enacted medical malpractice tort reforms; however, despite this legislation, malpractice premiums in the state have increased on average from 30% to 50% since 2000 (23). In 2003, Florida, after a second bout of tort reform measures, experienced an increase in insurance premium rates by as much as 45% (23).

This empirical evidence challenging the connection between tort reform and malpractice premiums is not just limited to the state of Florida. In 1995, the state of Texas passed legislation limiting the amount of punitive damages available in jury awards (24). Despite this measure, insurance premiums in the state continued to increase. These statistics cast doubts on the claim that tort reform is the most effective way to manage skyrocketing malpractice premium rates and reduce overall health care costs.

Defensive Medicine: Real or Imagined?

Tort reform proponents also typically cite the rise of defensive medicine as the other major negative residual effect of medical malpractice litigation. Those favoring medical malpractice tort reform argue that litigation-weary physicians order unnecessary and exhaustive tests on their patients, which, in turn, drives up the cost of health care. Empirical evidence appears to suggest, however, that both the impact and the prevalence of defensive medicine have been overstated.

Much of the support for the proposition that the practice of defensive medicine is the costly offshoot of medical malpractice litigation comes from a controversial 1996 study conducted by two Stanford University economists, Daniel Kessler and Mark McClellan. In this study, the economists analyzed the costs of care for hospitalized elderly Medicare patients with heart disease in states both with and without medical malpractice tort reforms (25). Based on their findings, Kessler and McClellan concluded that tort reforms resulted in hospital costs savings of 5% to 9% (25). The economists then applied these findings to the entire health care system, hypothesizing that tort reform could lead to a reduction of over $50 billion annually in health care expenditures (25). Tort reform supporters used this study to buttress their claim that without the ever-looming fear of litigation, physicians are freer to order fewer diagnostic tests, which, in fact, reduces their medical spending and lowers overall health care costs.

While Kessler and McClellan's findings became vindication for advocates of medical malpractice tort reform, subsequent research has criticized many of the hypotheses

contained within the study. In 2003, the U.S. Government Accountability Office (GAO) issued a statement questioning the applicability of Kessler and McClellan's findings to the entire health care system (26). The GAO's report argued that due to the limited scope of the study and its examination of patient behavior in the specific clinical situation of elderly patients with cardiac issues, "the study results cannot be generalized to estimate the extent and cost of defensive medicine practices across the health care system." (27) The report also concluded that while members of the medical community admitted that defensive medicine exists to some degree, the instance of its actual practice is extremely difficult to measure (27). This difficulty in quantifying the prevalence of defensive medicine in turn makes it more onerous to hypothesize any sort of costs savings for its reduction in practice.

More recent studies performed by the US government also reflect the tenuous connection between tort reform and its impact on the practice of defensive medicine. A 2004 study performed by the Congressional Budget Office (CBO) applied the methods employed by Kessler and McClellan's study to a wider set of medical ailments (26). It was concluded by the agency that there is no evidence linking restrictions on tort liability to reduced medical spending. A second analysis of the link between defensive medicine and health care costs performed by the CBO additionally confirmed no significant statistical difference in medical spending between states with and without medical malpractice tort limits (26).

One of the major reasons that medical malpractice tort reform has not definitively been found to effectively manage the practice of defensive medicine is because defensive medicine has been shown to be motivated by more than just a fear of litigation on physicians' parts. Some behavior that could be characterized as defensive medicine may be motivated more by the increased income additional diagnostic testing can generate for physicians, or the benefits a patient receives from additional testing, and less by fears of liability exposure (26). Additionally, it is unclear exactly how strongly concerns over medical malpractice liability actually affect a physician's treatment decisions. Physicians are highly educated professionals, who have to treat a patient's ailment based on myriad factors and considerations. To assume that all physicians require additional testing merely due to fears of liability exposure is unfounded.

Medical malpractice tort reform may also do little to curtail the practice of defensive medicine because empirical evidence seems to suggest that physicians typically have high levels of malpractice concern, in states both with, and without, tort reform. Research has shown that physicians in states with high malpractice risks have reported nearly the same level of concern over liability exposure as physicians in states with the low malpractice risks due to heightened medical malpractice tort reform (28). These results appear to be further evidence suggesting that tort reform in the context of medical malpractice may do little to assuage physicians' fears of liability or impact their diagnostic behavior in regard to the practice defensive medicine.

Risk Management

Although attempts to curtail medical malpractice litigation have been undertaken by many states with varying degrees of success, it is undisputed that this litigation has decreased over the last two decades. No matter the level of success in your state at instituting tort reform, however, medical malpractice litigation will never disappear entirely. As such, every solo practitioner or ENT practice group must focus its efforts at reducing risk by establishing a comprehensive risk management and compliance program to improve the safety and quality of the care that its physicians and employees provide. A key component of any program is the continuous assessment of quality management processes with a focus on implementing changes where necessary to ensure patient safety and the provision of high-quality and accurate medical care.

While specific areas of risk for otolaryngologists and how such risks can be minimized will be addressed later within this chapter, the structure of any risk management/quality and performance improvement program will certainly vary depending on the size of your particular practice group. It is widely accepted that with varying degrees of focus, depending on the size and structure of the practice or group, any risk management program must include the implementation of processes to monitor performance, implement change, and meet regulatory requirements in the areas of patient safety, process improvement, quality, and professional staff education and assessment.

Importantly, although voluntarily implementing these quality-related programs in order to reduce exposure to allegations of medical malpractice is necessary for any ENT practice or group to succeed, many of these processes are required by the very organizations that regulate the otolaryngology profession—thus making such implementation of these programs mandatory.

For example, the American Board of Otolaryngology Maintenance of Certification (MOC) program is for diplomats who are working in their ten (10)-year cycle of maintaining their certification. Although the specific requirements of the competencies and components of each MOC program will depend on an ENT's particular practice area, the MOC program generally evaluates four (4) essential competencies on a continuous basis including (a) professional standing, (b) continuing education/self-assessment, (c) cognitive examination, and (d) performance in practice (29). Evaluation of these competencies seeks to ensure that high standards of health care quality are maintained throughout the ENT practice as a whole, and these exacting quality requirements serve to minimize exposure to individual physicians from the overall risk of medical negligence claims. Other organizations with compliance and regulatory quality requirements include

the Joint Commission on Accreditation of Healthcare Organizations and the Accreditation Council for Graduate Medical Education.

Thus, it is clear that every otolaryngology practice, department, or group must focus considerable effort and time in the development and maintenance of a comprehensive quality, risk management, and compliance program to improve patient safety and quality of care not only for the welfare of patients and to maintain a competitive edge but to reduce the ever-present risk of and exposure related to medical malpractice.

COMPLIANCE AND REGULATORY ISSUES

Introduction to Federal Health Care Fraud and Abuse Laws

It is unquestionable that billing and reimbursement have become integral parts of the practice of medicine. It is also unquestionable that few people would devote at least 9 years of their lives to become an otolaryngologist with the intent to cheat the federal government in their billing of medical claims. Various factors, such as greed or carelessness, may contribute to improper behavior by physicians during their careers, but ignorance of the law need not be one of those factors.

Although maintaining proper financial dealings with federal health care programs in the current health care environment is part of being a physician, medical schools and residency programs do not uniformly teach trainees about fraud and abuse. Indeed, in 2010, the Office of the Inspector General (OIG) surveyed all medical school deans and designated officials for institutions that sponsor residency and fellowship programs to determine whether their institutions provide education about fraud, waste, and abuse; to identify knowledge gaps; and to determine how the OIG could best promote education about compliance with the relevant laws. The survey revealed that less than half of the nation's medical schools provide instruction on fraud and abuse (30).

Violating the fraud and abuse laws can result in criminal penalties; civil fines; exclusion from the federal health care programs, which include Medicare and Medicaid; and even loss of your medical license by your State Medical Board. Thus, a good understanding of the five most important federal fraud and abuse laws that apply to physicians is essential.

Enforcement

Three federal government agencies are charged with enforcing the fraud and abuse laws: the Department of Justice, the Department of Health & Human Services Office of the Inspector General (OIG), and the Centers for Medicare & Medicaid Services (CMS). The five laws include the Physician Self-Referral Law (Stark Law), Antikickback Statute (AKS), the False Claims Act, the Exclusion Authorities, and the Civil Monetary Penalties Law.

Physician Self-Referral Law (Stark Law)

The Physician Self-Referral Law,[12] commonly referred to as the Stark Law, (a) prohibits a physician from making referrals of certain designated health services (DHS) payable by Medicare or Medicaid to an entity with which he or she (or an immediate family member) has a financial relationship (ownership or compensation) unless an exception applies[13] and (b) prohibits the entity from filing claims with Medicare or Medicaid (or billing another individual, entity, or third party payor) for those referred services, unless an exception applies. When originally enacted in 1989, the law applied only to physician referrals for clinical laboratory services. In 1993 and 1994, Congress expanded the prohibition to include additional DHS.

DHS now include (a) clinical laboratory services; (b) physical therapy, occupational therapy, and speech–language pathology services; (c) radiology and certain other imaging services; (d) radiation therapy services and supplies; (e) durable medical equipment and supplies; (f) parenteral and enteral nutrients, equipment, and supplies; (g) prosthetics, orthotics, and prosthetic devices and supplies; (h) home health services; (i) outpatient prescription drugs; and (j) inpatient and outpatient hospital services.

Significantly, the Stark Law is a strict liability law, which means that proof of specific intent to violate the law is not required. If Stark is triggered, and an exception is not met, a health care provider will be subject to severe sanctions, including denial of filing claims for those referred services, civil monetary penalties, exclusion from Medicare and Medicaid, and potential False Claims Act liability.

Antikickback Statute

The AKS[14] makes it a criminal offense to knowingly and willfully offer, pay, solicit, or receive any remuneration to induce or reward referrals of items or services reimbursable by a federal health care program. Where remuneration is paid purposefully to induce or reward referrals of items or services payable by a federal health care program, the AKS is violated. By its terms, the statute ascribes criminal liability to parties on both sides of an impermissible "kickback"

[12] 42 U.S.C. §1395nn.

[13] Stark Law contains approximately 35 exceptions that describe acceptable financial relationships that allow a physician to refer to an entity for the provision of designated health services (42 CFR Part 411, Subpart J). Some commonly applied exceptions to the Stark Law include the exceptions for personal services, bona fide employment relationships, physician recruitment, and physicians practicing in rural areas and locations designated as Health Professional Shortage Areas. Each of the exceptions to the Stark Law has numerous elements that must be met in order to qualify for the exception, and care should be taken to assure compliance with each of these elements.

[14] 42 U.S.C. §1320a-7b(b).

transaction. For purposes of the AKS, "remuneration" includes the transfer of anything of value directly or indirectly, overly or covertly, in cash or in kind.

The AKS has been interpreted to cover any arrangement where one purpose of the remuneration was to obtain money for the referral of services or to induce further referrals (31). With the passing of the Patient Protection and Affordable Care Act (PPACA)[15] on March 23, 2010, the AKS "intent" element was revised to remove any specific intent or actual knowledge of an AKS violation. Thus, one does not have to have "knowingly" and "willfully" violated the AKS to make the kickback actionable. Violation of the AKS constitutes a felony punishable by a maximum fine of $25,000, imprisonment up to 5 years, or both. Conviction will also lead to mandatory exclusion from federal health care programs, including Medicare and Medicaid. PPACA[16] also expanded the punishment for violation of the AKS Statute adding that any AKS violation is now a false claim under the False Claims Act, subjecting the provider to civil penalties.

Due to the breadth of the potential application of the AKS, the OIG was required to develop "safe harbor" regulations designed to protect various payment and business practices because such practices would be unlikely to result in fraud or abuse.[17] If an arrangement falls outside of the safe harbor, it is not *per se* illegal, but the facts and circumstances behind the arrangement must be carefully reviewed. The safe harbors set forth specific conditions that, if met, assure entities involved that they will not be prosecuted or sanctioned for the arrangement qualifying for the safe harbor. However, safe harbor protection is afforded only to those arrangements that precisely meet all of the conditions set forth in the safe harbor.

False Claims Act

False Claims Act violations occur when claims are submitted for payment to Medicare or Medicaid that are false or fraudulent. No specific intent to defraud is required. Filing false claims may result in civil penalties of not less than $5,500 and not more than $11,000 for each claim plus three times the programs' loss. Significantly, each instance of an item or a service billed to Medicare or Medicaid counts as a claim; thus, the potential fines can add up quickly. Moreover, a claim that results from a kickback or is made in violation of the Stark Law may also render it false or fraudulent, creating liability under the False Claims Act in addition to the AKS and the Stark Law.

The OIG may initiate administrative proceedings to impose civil monetary penalties and may also initiate administrative proceedings to exclude a party that files a false claim from the federal health care programs. There is also a criminal False Claims Act,[18] which imposes criminal penalties for submitting false claims including imprisonment and criminal fines.

Exclusion Statute[19]

The OIG is required to exclude from participation in all federal health care programs individuals and entities convicted of criminal offenses including (a) Medicare or Medicaid fraud, (b) patient abuse or neglect, and (c) felony convictions for health care–related fraud, theft, financial misconduct, unlawful manufacture, distribution, prescription, or dispensing of controlled substances. The OIG has discretion to exclude individuals and entities on several other grounds. In recent years, the OIG has been exercising its permissive exclusion power with much more frequency in order to combat health care fraud. As of January 2011, more than 5,000 physicians were excluded from participation in the federal health care programs because of these types of violations and cannot treat any of the approximately 100 million Medicare and Medicaid beneficiaries.[20]

Exclusion from participation in the federal health care programs is devastating to any career. The federal programs will not pay the provider for items or services furnished, ordered, or prescribed. As a result, providers may not bill Medicare or Medicaid directly for treating patients nor may their services be billed indirectly through their group practice. Moreover, once excluded from the federal health care programs, it is likely that other third party payors will follow suit, disallowing the excluded provider from submitting claims for reimbursement. As such, an excluded provider will be unemployable as the provider will be unable to receive payment for services rendered from the federal health programs. Unfortunately for such providers, it is impossible to hide from the reality of being excluded as the OIG maintains a List of Excluded Individuals and Entities on its Web site, which can be found at http://oig.hhs.gov/fraud/exclusions.asp.

Civil Monetary Penalties Law[21]

The Civil Monetary Penalties Law grants the OIG the authority to seek civil monetary penalties and, in some instances, exclusion, for a wide variety of conduct. Violations of the law includes violating AKS, presenting claims that the persons knows or should have known is for an item or service that was not provided as claimed or is false or fraudulent or for which payment may not be made. Penalties range from $10,000 to $50,000 per violation and, possibly, exclusion from the federal health programs.

Application of the Laws

Given that the health care environment has drastically changed over the years, physicians of all experience levels must understand the fraud and abuse laws and how they influence the way medicine is practiced. This is particularly true since physicians must understand that they are personally liable for claims submitted under their national provider identifiers regardless of whether or not they personally code or bill the services. Although a physician can certainly delegate such tasks from a business and administrative perspective, the physician continues to have a significant stake in ensuring compliance. Some physicians are surprised to learn that every CMS 1500 form that is submitted contains a certification statement wherein the physician personally attests that the services were medically necessary and that (absent an exception permitted under the regulations) he or she personally furnished the service.

The key to avoiding violations of the fraud and abuse laws is to have a clear understanding of how they shape and control the three "most common" relationships that physicians encounter in their careers: relationships with payors (like the Medicare and Medicaid programs), relationships with vendors (like drug, biologic, and medical device companies), and relationships with fellow providers (like hospitals, nursing homes, and physician colleagues).

Physician Relationships with Payors

Physicians need to develop and maintain systems in their practice to oversee that they are accurately coding and billing for services rendered to patients and diligently maintaining accurate and complete medical records and documentation to support the fact that the services billed for were necessary and have actually been provided. Physicians must also avoid the misuse of their physician and prescription provider numbers and understand the strict requirements of the Medicare reimbursement rules as a participating or nonparticipating provider. In addition to the fraud and abuse implications resulting from poor documentation practices, physicians should keep in mind that the primary reason for denial in postpayment audit cases (e.g., Medicare audits requesting refunds of alleged overpayments) typically relates to documentation deficiencies. Enhancement of documentation practices in any physician practice should unquestionably be a top priority.

Physician Relationships with Fellow Providers: Physicians, Hospitals, Nursing Homes, Etc.

Within these relationships, physicians must steer clear of any situation in which their decision-making with respect to patient referrals or use of products or services is based on anything other than what is medically necessary and appropriate for the patient. As most physicians have figured out by now, the fraud and abuse laws are complicated; however, physicians are held accountable for ensuring that relationships are structured in a compliant manner. Physicians can avoid the pitfalls of improper arrangements by making sure that they appropriately consult with experts prior to entering into the relationship. Unfortunately, the fact that a physician was unaware of the implications of the fraud and abuse laws to the relationship is not a legitimate defense.

Physician Relationships with Vendors

A particular area of vulnerability for physicians involves relationships with pharmaceutical and medical device industries. Like physician relationships with fellow providers, physicians must steer clear of allowing the pharmaceutical or medical device industries from buying their loyalty or otherwise inducing them to prescribe or use products based on anything other than what is a medical necessity. The OIG offers some practical questions a physician should self-inquire to test the propriety of any proposed compensation relationship with these entities:

- Does the company really need my particular expertise or input?
- Does the amount of money the company is offering seem fair, appropriate, and commercially reasonable for what it is asking me to do?
- Is it possible the company is paying me for my loyalty so that I will prescribe its drugs or use its devices? (32).

Physicians can also review the OIG's Compliance Program Guidance for Pharmaceutical Manufacturers available at www.oig.hhs.gov/authorities/docs/03/050503FRCPGPharmac.pdf. Moreover, in protecting oneself in these relationships, one must keep in mind that under the PPACA,[22] transparency is coming in the form of requiring drug, device, and biologic companies to publicly report nearly all gifts or payments they make to physicians beginning in 2013.

Compliance Programs

Prior to PPACA, health care providers were encouraged but not required to maintain compliance programs to help ensure their compliance with fraud and abuse laws and federal health program requirements. Under PPACA, if you treat Medicare and Medicaid beneficiaries, you are required to establish a compliance program.[23] Seven

[22]Pub. L. 111-148 was signed into law on March 23, 2010.

[23]Section 6401(a). On February 2, 2011, the Centers for Medicare and Medicaid Services ("CMS") published its final rule for establishing new screening requirements for enrollees in Medicare, Medicaid, and the Children's Health Insurance Program ("CHIP") pursuant to Section 6401(a) of PPACA (the "Final Rule") (76 FR 5941). The Final Rule also addressed the compliance program requirement as set forth in Section 6401 of PPACA, which prescribes that, as a condition of enrolling in Medicare, Medicaid, or CHIP, providers and suppliers must establish compliance programs that meet certain "core elements." Notably, however, CMS did not finalize any rules related to mandatory compliance. Instead, CMS noted in the Final Rule that it would continue to do further rule making and would "advance specific proposals at some time in the future."

components to establishing a "solid" compliance program include (a) conducting internal monitoring and auditing, (b) implementing compliance and practice standards, (c) designating a compliance officer or contact, (d) conducting appropriate training and education, (e) responding appropriately to detected offenses and developing corrective action, (f) developing open lines of communication with employees, and (g) enforcing disciplinary standards through well-publicized guidelines.

Notwithstanding the PPACA mandates, in recognition of the increase in enforcement and audit activity, now, more than ever, it is imperative that every physician have in place an effective compliance program that is tailored to his/her particular practice and specialty.

THIRD PARTY PAYOR AUDITS

Third Party Payor Audit(s) Overview

Physicians submitting claims to all third party payors (i.e., Medicare, Medicaid, and private payors) must be cognizant that all claims are under unprecedented payor scrutiny. In an effort to protect the integrity of the Medicare and Medicaid Trust Funds, as well as the bottom line of private insurers, all payors are actively auditing claims. Health care providers must be mindful of this increased claims scrutiny and conduct themselves accordingly.

With respect to claims submitted to Medicare, not only do Medicare Administrative Contractors (MACs) (and/or Medicare Carriers and Intermediaries) conduct their own audits, but also the CMS contracts with various other entities to perform Medicare auditing functions. For example, Medicare's Recovery Audit Contractor (RAC) program is now operational nationwide (and has been expanded to include Part C and Part D claims). RAC auditors are tasked to identify and correct all types of improper Medicare payments and are compensated on a contingency fee basis. In addition, Zone Program Integrity Contractors (ZPICs) (or Program Safeguard Contractors ["PSCs"]) are actively conducting benefit integrity audits nationwide.

With respect to Medicaid claims, in addition to each state conducting their own Medicaid audits, there also exist federal Medicaid auditing programs. Under the Medicaid Integrity Program, Audit Medicaid Integrity Contractors (MICs) are auditing Medicaid claims in every state. The focus of the Audit MICs is on providers with "truly aberrant" claim submissions. In addition, the nationwide RAC program has been expanded to also include Medicaid claims.

Which Physicians Are Likely to Be Audited?

All auditors (Medicare, Medicaid, and private payors) use proprietary "data mining" techniques to determine claims likely to constitute overpayments and to identify providers with utilization patterns that may suggest overpayments to be occurring. Therefore, physicians providing a high volume of higher-cost procedures, or physicians with a noticeable volume of high-level office visits (e.g., a high volume or level 4 or level 5 office visits), may find themselves under increased claims scrutiny. As noted elsewhere herein, through various guidance documents (e.g., the RAC-approved issues lists), CMS indicates claims likely to be subject to increased scrutiny under the Medicare and Medicaid programs. Physicians submitting these types of claims may see more auditing activity. Moreover, physicians should identify risk areas specific to his or her field of practice. These areas are often identified in specialty publications and can be found in third party payor guidances, local medical review policies, OIG guidances, fraud alerts, and the annual OIG work plan. One such area that has been a significant focus of the enforcement authorities and third party payors is E & M (or Evaluation and Management) services. In addition, physicians can discover their own personal practice risk areas by conducting self-audits focusing on, for example, the ten (10) most-often billed procedures and/or the ten (10) procedures yielding the highest practice revenue, looking at published policies and guidelines for these procedures, meeting with other providers in the physician's office and the billing staff, and discussing the documentation and billing of these procedures.

When conducting such audits, there are a number of significant items to consider. For example, (a) whether the audit should be prospective as opposed to retrospective, (b) whether the audit should be conducted for general educational purposes or for specific reasons (e.g., to quantify a suspected error), (c) whether one should use external auditors or internal auditors, (d) the sample size of the audit, (e) which documents to review, and (f) how often to perform the audit. Importantly, it is highly recommended that any self-audit be done at the direction of legal counsel—not only to help one decide the best manner in which to conduct the audit and to address the aforementioned items, but also to avoid providing a "road map" of any problems revealed by the audit to the enforcement authorities. Self-audits that are not directed by legal counsel are not protected by the attorney work product doctrine and/or attorney–client privilege and thus are discoverable by the enforcement authorities who can use the findings against the physician.

Typical Audit Processes for Medicare

Generally speaking, Medicare audits are conducted to determine whether claims are or were properly submitted to Medicare. When Medicare audits are conducted for medical review purposes, the contractor's focus is to determine whether services are covered, are reasonable and necessary, and are correctly coded. When Medicare audits are conducted for benefit integrity purposes, the focus is different (e.g., looking for possible falsification). Medicare audits may be conducted on either a prepayment or postpayment

basis and may be conducted either on-site or via "desk audit."

When initiating either a prepayment review or postpayment audit for medical review purposes, a Medicare contractor is required to issue a written notification to the physician, which includes the following elements:

1. That the physician has been selected for prepayment review or postpayment audit and the reason for the selection. If the reason the physician was selected for audit was comparative data, then the Medicare contractor should provide the comparative data to the physician as part of this notification.
2. Whether the review will be conducted on a prepayment or postpayment basis
3. If postpayment audit, a list of claims requiring medical records to be produced (including the time frames for returning additional documentation—typically 30 to 45 days)

Note: It is essential that physicians adhere to the time frames for submitting requested documentation. If the time frames are not met, the Medicare contractor will deny the subject claims. The contractor thereafter may, but is not required to, reopen the claims upon appeal.

Generally speaking, prepayment review(s) or postpayment audit(s) is conducted within 60 days from receipt of requested medical records.[24] When reviewing claims, the Medicare contractor will use both published Medicare guidance (e.g., National Coverage Decisions (NCDs), Local Coverage Decisions (LCDs), CMS Manuals, CMS Coding Articles, etc.), and internal review guidelines. In a postpayment audit, following the review, the Medicare contractor will prepare a letter to notify the physician regarding the results of the audit, including the rationales for denials and information regarding the statistical extrapolation performed, if applicable. The physician also will receive a demand letter, which triggers relevant appeal deadlines. Prepayment review results will be communicated via Remittance Advice.[25]

The Medicare Appeals Process

Part A and Part B Medicare claim denials arising from Medicare audits are subject to the five-stage appeals process set forth at 42 C.F.R. Part 405, Subpart I. It is essential from a business perspective that physicians understand this appeals process and appeal claim denials as they occur. Denials may be successfully overturned in the Medicare appeals process, resulting in monies returned to the physician. The five-stage appeals process is as follows:

1. *Stage 1: Redetermination*. The first level in the appeals process is redetermination. There is no amount in controversy requirement. Providers must submit redetermination requests in writing within 120 calendar days of receiving notice of initial determination.

   Significantly, federal law prohibits Medicare from recouping an alleged overpayment during the first two stages of the appeals process (i.e., during the redetermination and reconsideration stages of appeal). Although federal regulations grant physicians 120 calendar days to file a request for redetermination, Medicare will begin recouping the alleged overpayment arising from a Medicare audit prior to the expiration of the 120-day appeals time frame if a valid request for redetermination is not first received. Specifically, recoupment will begin on the 41st day from the date of the notice of initial determination, unless a valid request for redetermination is received 30 days following the date of notice of initial determination. If this time frame is not met, Medicare will stop recoupment at whatever point an appeal is received, but it will not refund any amounts withheld prior to that time.
2. *Stage 2: Reconsideration*. Physicians dissatisfied with a redetermination decision may file a request for reconsideration to be conducted by a Qualified Independent Contractor (QIC). A QIC is a Medicare contractor tasked to complete this second level of appeal (reconsideration level of appeal). There is no amount in controversy requirement. This second level of appeal must be filed within 180 calendar days of receiving notice of the redetermination decision.

   Although federal regulations grant physicians 180 calendar days to file a request for reconsideration, Medicare will again begin recouping its alleged overpayment following the redetermination stage prior to the expiration of the 180-day appeals time frame if a valid request for reconsideration is not first received. Specifically, recoupment may begin on the 61st day from the date of redetermination decision, unless a valid request for reconsideration is received. If this time frame is not met, Medicare will stop recoupment at whatever point an appeal is received.

   Significantly, physicians must submit a "full and early presentation of evidence" in the reconsideration stage. When filing a reconsideration request, a physician must present evidence and allegations related to the dispute and explain the reasons for the disagreement with the initial determination and redetermination. Absent good cause, failure of a physician to submit evidence prior to the issuance of the notice of reconsideration precludes subsequent consideration of the evidence. Accordingly, physicians may be prohibited from introducing evidence in later stages of the appeals process if such evidence is not presented at the reconsideration stage.

[24]This 60-day time period does not apply to reviews for benefit integrity purposes (PSC or ZPIC audits).

[25]*See generally*, Medicare Program Integrity Manual (CMS Pub. 100-08), Chapter 3, Section 30.4 *et seq.*

3. *Stage 3: Administrative Law Judge (ALJ) Hearing*. A provider dissatisfied with a reconsideration decision may request an ALJ hearing. The request must be filed within 60 days following receipt of the QIC's decision and must meet an amount in controversy requirement. ALJ hearings can be conducted by video teleconference (VTC), in person, or by telephone. The regulations require the hearing to be conducted by VTC if the technology is available; however, if VTC is unavailable or in other extraordinary circumstances, the ALJ may hold an in-person hearing. Additionally, the ALJ may offer a telephone hearing.
4. *Stage 4: Medicare Appeals Council (MAC) Review*. The fourth level of appeal is the Medicare Appeals Council (MAC) Review. The MAC is within the Departmental Appeals Board of HHS. A MAC Review request must be filed within 60 days following receipt of the ALJ's decision. Among other requirements, a request for MAC Review must identify and explain the parts of the ALJ action with which the party disagrees. Unless the request is from an unrepresented beneficiary, the MAC will limit its review to the issues raised in the written request for review.
5. *Stage 5: Federal District Court*. The final step in the appeals process is judicial review in federal district court. A request for review in district court must be filed within 60 days of receipt of the MAC's decision and meet an amount in controversy requirement.

Audit Defenses

In preparing a Medicare appeal, physicians should both challenge the merits of the claim denials and employ applicable legal defenses. In arguing the merits, physicians should prepare a position paper and/or a summary of the documentation relevant to the claims at issue, setting forth the justification for the services as billed. Attached to the position paper should be all records supporting the claims at issue, organized in a user-friendly manner. Note that this likely will involve more records than just the records for the specific dates of service denied. For example, if a procedure is denied, the submitted documentation should include any office visit preceding the procedure supporting the medical necessity for the procedure. In arguing the merits of the claim, physicians should engage the services of a qualified medical/coding/statistical expert, as applicable. In addition to arguing the merits, physicians may choose to employ the following legal defenses, as applicable:

1. *Provider without Fault*: As a general rule, a provider will be considered without fault if it exercised reasonable care in billing for and accepting payment (i.e., it complied with all pertinent regulations, made full disclosure of material facts, and, on the basis of the information available, had a reasonable basis for assuming that the payment was correct). A provider or supplier will be presumed to be without fault if an overpayment is discovered subsequent to the third year following initial determination.[26]
2. *Waiver of Liability*: In the event a Medicare contractor denies a service as not medically reasonable and/or necessary, the denial constitutes a denial under Section 1862 (a) of the Social Security Act, subjecting the claims to waiver of liability consideration. The statutory authority for the application of Waiver of Liability is set forth in Section 1879 (a) of the Social Security Act. Generally speaking, once waiver of liability applies, the relevant inquiry focuses on whether the provider or supplier knew or could have reasonably been expected to know that payment would not have been made for the services.
3. *Treating Physician's Rule*: The legal theory of the Treating Physician's Rule provides that the treating physician's determination that a service is medically necessary and appropriate should predominate over a reviewer's determination.
4. *Challenges to Statistics*: Providers may also legally challenge the statistics in connection with extrapolated audits. This will involve the retention of a qualified statistical expert to review the statistical sample and extrapolation performed for compliance with Medicare guidelines. Challenging the statistical extrapolation performed (which, if successful, would bring the overpayment demand to the "actual" overpayment, rather than the projected overpayment) should be a key focus of any appeal where a statistical extrapolation is performed.[27]

Compliance Tips

Although physicians may not be able to prevent a Medicare audit from occurring, physicians should prepare for increased claims scrutiny and audit activity by dedicating resources to the following:

1. Regularly *monitoring* guidance documents educating physicians regarding the types of claims subject to increased Medicare claims scrutiny, including historical audit data (such as the review results arising from the RAC Demonstration Program), the RACs' Web sites identifying approved audit issues (links available from www.cms.hhs.gov/RAC), the OIG Work Plan, etc.

   Note that the RAC demonstration program did not focus on ENT physicians specifically; thus, a review of the RAC demonstration results is not particularly helpful for ENT physicians with the exception of vestibular

[26]Section 1870 of the Social Security Act. *See also* Medicare Financial Management Manual, CMS 100-06, Chapter 3, Section 70 *et seq*.
[27]*See* Section 1893 of the Social Security Act and Medicare Program Integrity Manual, CMS Pub. 100-08, Chapter 3, Section 3.10 *et seq*.

function testing.[28] As of the date of publication of this chapter, the RACs' Web sites did include certain ENT physician-specific issues presently under RAC review (e.g., the RACs are presently reviewing certain E & M issues). These Web sites should be continuously monitored as Medicare approves additional areas for RAC review. A review of other guidance documents, such as the OIG Work Plan, will be helpful to identify areas that may be subject to scrutiny. For example, the 2011 OIG Work Plan states that payments for E & M services will be subject to scrutiny in 2011.

2. *Reviewing* and educating physicians regarding any Medicare NCDs and LCDs applicable to claims submitted by the physicians
3. *Designating* an audit "point person" responsible to monitor communications from Medicare and its contractors, which will include monitoring records requests and ensuring that such requests are responded to within the requisite time frames
4. *Implementing* compliance efforts, including but not limited to (a) educating staff members regarding the potential business impact of Medicare audits and the corresponding importance of compliance and appropriate response to records requests and claim determinations and (b) performing documentation and coding education. Documentation and coding education may entail engaging a qualified health care legal professional and coding professional to conduct a formal compliance audit of high-risk claims.
5. *Tracking* claim denials, monitoring and abiding by appeal deadlines, and properly working up appeals to challenge denials in the appeals process

PHYSICIAN LICENSING ACTIONS AND THEIR COLLATERAL EFFECTS

Introduction

Whether an otolaryngologist is a medical doctor or an osteopath, his or her ability to practice in any given state within the United States (other than at a federal institution such as a VA hospital) is governed by the laws of that state. While some states allow a physician who is not licensed in their particular state, but who is licensed in another state in good standing, to practice in their state under certain special circumstances (e.g., in an educational setting or in emergency circumstances), the far majority of the time a physician must be compliant with the laws, rules, and regulations of each state in which the physician practices. Physicians will be deemed to have constructive knowledge of such laws, rules, and regulations regardless of whether he or she has actual knowledge thereof. As such, it is imperative for a physician seeking licensure in a given state to become familiar with that state's governing laws, rules, and regulations, especially since there are some significant differences (e.g., in some states there are express prohibitions against prescribing medication to family members regardless of the circumstances, whereas in other states, such prescribing is allowed as long as the physician determines that he or she can maintain objectivity when treating the patient). Typically, states have boards of medicine that promulgate administrative rules and guidance to which physicians should adhere, in addition to public health codes and other statutory and case law, in order to avoid disciplinary action taken against a physician's license. Some states have one board of medicine that governs both medical doctors and osteopaths while other states have separate boards for each—although the rules and guidance for medical doctors often mirror those for osteopaths. These medical boards are administrative agencies often composed of not just physicians but other health care providers and members of the public appointed by state executive officials (such as the governor) and serve to govern the medical profession and help to protect the health, safety, and welfare of the public.

The bases for disciplinary action are often codified by statutory law in each state and are enforced by the state's medical board. Some bases may be very specific (e.g., violation of a particular state statute regarding prescribing a medication for an illegitimate, nontherapeutic purpose), while other bases are rather broad (e.g., acting outside the applicable standard of practice). An important distinction for physicians to keep in mind is the difference between a licensing action and a medical malpractice action. In a medical malpractice action, the physician's actions or omissions must cause damages for liability to arise. In a licensing action, causing damages is not a requisite element. As such, a physician may find himself/herself subject to a licensing action for failing to document information where the applicable standard of practice requires such documentation in the medical record even though the lack of documentation did not result in any harm to a patient.

How Licensure Actions Arise

An action against a physician's license typically arises from a complaint filed with the state medical board by a person or entity with firsthand knowledge of alleged wrongdoing by the physician (e.g., a patient, employee, or employer of the physician). Some states allow for completely anonymous complaints while others require the complainant to identify himself or herself in order to commence an investigation. In some scenarios, the complainant is the court clerk who under legal authority is required to report to the medical board when a physician is convicted of a crime

[28]The majority of physician claim denials made during the RAC demonstration program involved pharmaceutical injectables, Neulasta (incorrect coding), Vestibular function testing, and duplicate claims. *See* "The Medicare Recovery Audit Contractor (RAC) Program: An Evaluation of the 3-Year Demonstration," *available at* http://www.cms.gov/RAC/Downloads/RACEvaluationReport.pdf.

or an alcohol- or drug-related offense. In some states, the complainant may be the physician's medical malpractice defense attorney who is required to report to the medical board a verdict or settlement against the physician in a medical malpractice action. The complainant may be a hospital where the physician had his or her medical staff privileges reduced, limited, suspended, or revoked or employment terminated. The physician himself or herself may even be the complainant as, in nearly every state, the physician has a duty to self-report a disciplinary action or criminal conviction against the physician in another state within a certain prescribed time frame (e.g., 30 days from the date of the final order or conviction).

Typical allegations asserted against a physician are for quality of care concerns, a scope-of-practice concern issue or the conduct of the physician—which may include potential criminal conduct (e.g., a patient who is billed for services that he or she never received may submit a written allegation against the physician to the applicable state medical board). After receiving an allegation, the medical board typically reviews it and determines whether the alleged facts, if true, could be deemed a violation of the state's public health code or other statutory laws or case law and thereby warrant an investigation.

An investigation into an allegation usually involves interviewing the person filing the allegation, interviewing the physician, identifying and interviewing other persons such as coworkers or employers who may provide relevant information, and collecting other evidence.

Administrative Complaint and Hearing

If the medical board determines that there is sufficient evidence to demonstrate a violation of the applicable public health code or law, a formal administrative complaint is typically filed by the state against the physician (often called the "licensee" in such matters) charging the physician with specific statutory violations or other violations of the law.

Nearly every state also provides the medical board with grounds for the issuance of an administrative complaint for numerous preceding criminal violations. For example, a conviction of any criminal sexual conduct; reckless or intentional inappropriate destruction or alteration of medical records; a misdemeanor or felony involving fraud to obtain professional fees; a misdemeanor related to the ability to practice safely/competently; and practicing under the influence of alcohol or drugs in many states provides a basis for a licensing action against the convicted physician.

Since the state medical board is charged with protecting the health, safety, and welfare of its citizens, if the medical board believes that there could be an immediate risk to the public health, safety, or welfare, it may order a summary suspension of the physician's license until an administrative hearing is held. Under such circumstances, the physician must immediately cease practicing medicine even before he or she is given an opportunity to defend his or her actions and cannot practice medicine until otherwise authorized to do so by the medical board. Summary suspension typically occurs where the physician is convicted of a felony or a misdemeanor involving the illegal delivery, possession, or use of a controlled substance.

The procedures to be followed after the issuance of an administrative complaint differ from state to state; however, they typically require the physician to file an answer to the administrative complaint and provide the licensee an opportunity to meet with members of the medical board to attempt to reach a resolution of the administrative complaint short of attending a formal administrative hearing. These procedures usually have specific deadlines associated with answering the administrative complaints, requesting and attending settlement conferences and other procedures for which failure to comply can have severe adverse consequence for the physician (e.g., failing to timely answer an administrative complaint in some states results in all of the allegations being deemed admitted and the matter goes straight to the medical board for imposition of sanctions against the physician). Proposed settlements usually require formal approval by the medical board and are typically available to the public.

If a settlement cannot be reached, the matter proceeds to an administrative hearing to be conducted in accordance with established state administrative procedures and rules governing the conduct of the hearing, introduction of evidence, and the examination of witnesses. The purpose of the hearing is to determine the facts of the case and the laws and rules that should be applied to the case. Should the physician be found to have violated the applicable state laws, sanctions will be imposed upon the physician and/or his or her license, which can include a monetary fine, probation, reprimand, restriction on the license, additional medical education beyond the standard requirements for continuing medical education, community service, and/or suspension or revocation of the license.

Licensing Actions May Lead to Criminal Prosecution

While state public health codes have numerous grounds upon which the medical boards may rely for the issuance of an administrative complaint, some provisions are more apt to lead to criminal prosecution, for example, allegations of an inappropriate sexual relationship with a patient, a pattern of providing controlled substances without medical necessity, a pattern of fraudulent billing, and a pattern of performing medically unnecessary procedures for personal financial gain. All of these offenses typically fall within express provisions of state public health codes giving rise to a licensing action and also fall within the ambit of numerous state and federal criminal statutes, thereby leaving the physician exposed to potential criminal prosecution.

Furthermore, it is important to understand that some actions by physicians subsequent to being served with an Administrative Complaint may also lead to criminal prosecution. One common allegation contained within an administrative complaint is that the physician violated his or her general duty due to inadequate, insufficient and/or missing documentation. Such an allegation can lead a concerned physician to attempt to "correct" the situation by creating records where none existed or supplementing the records to address the alleged inadequacy or insufficiency without including sufficient information to make it clear when these new records were added. Such action by a physician is typically a felony under state statutory law.

When defending a health care licensing matter, it is important to always consider the possibility of criminal exposure for the subject physician. Such consideration is integral to the decision of whether to have the physician testify at an administrative hearing. Physicians have to weigh the risk of asserting their Fifth Amendment rights against self-incrimination in order to avoid having admissions made during administrative proceedings that could be used against them in a criminal matter.

A physician facing a health care investigation or an administrative action by a state medical board cannot afford to take a myopic view of his or her predicament. Due to the criminal implications and the domino effect that often accompanies the imposition of state-imposed sanctions, such physician are well advised to obtain experienced health care counsel as early as possible in the process who will take an expansive view of the matter in order to assess the collateral damage that could result from a proposed settlement of a state action. Although most attorneys are knowledgeable enough to inform their clients of their Fifth Amendment rights against self-incrimination in order to avoid having their clients make any admissions during the administrative proceedings, which could lead to criminal charges, many attorneys are unaware of the effects that collateral sanctions may have on their clients. Any settlement strategy should take into consideration all of the collateral sanctions and enforcement actions that could arise as a result of a settlement.

Collateral Effects of a Licensing Action Other Than Criminal Prosecution

In addition to the aforementioned potential for criminal prosecution, there are numerous consequences and collateral effects that a licensing action may have on a physician. Any sanctions imposed upon the physician are typically published online and in the state's disciplinary action report, and notice of the sanctions is sent to numerous state and federal authorities (which, for physicians, may include the National Practitioner Data Bank), along with applicable professional associations, and various national and local news associations (e.g., the Associated Press and the United Press International). The severity of the sanction imposed by the state medical board will determine the extent of the collateral damage to the physician. The following is a list of some, but not all, of the repercussions that a sanctioned physician may encounter: loss of hospital privileges, loss of participation and enrollment with state professional associations, loss of participation in preferred provider organizations (PPOs), loss of enrollment with third party payors, loss of DEA registration, loss of board certification, and exclusion from participation with Medicare, Medicaid, and other federal and state government programs.

As noted above, nearly every state requires a physician who is disciplined in another state to report such discipline to their state. Thereafter, such state has the right to file its own disciplinary action against the physician even though all of the facts and circumstances that gave rise to the original disciplinary action took place in the other state. As a result, the derivative state may impose even a harsher sanction against the physician than the sanction imposed by the originating state depending upon the laws, policies, politics, and mind-set of the derivative state.

Conclusion

Unfortunately, some physicians fail to appreciate the serious magnitude of an allegation filed against them with their state licensing body. Whether a physician is contacted directly by an investigator or whether he or she hears from a patient or an employee that an investigator has been asking questions regarding the professional behavior/conduct of the physician, the physician should immediately contact an experienced and knowledgeable health care attorney to provide assistance and guidance at the earliest possible stage. All too often, physicians believe that they can explain away or justify the alleged inappropriate behavior/conduct only to learn later on that such admissions are used as direct evidence against them to support a sanction against his or her health care license. Moreover, depending on the severity of the sanction imposed, there are numerous collateral effects that a state licensing action may have on the physician, including, but not limited to

1. Loss of hospital privileges and/or employment
2. Loss of enrollment with state professional associations and their associated benefits (e.g., health, disability, and life insurance)
3. Loss of participation in PPOs and other third party payors
4. Loss of DEA registration, state-controlled substance licenses, and other health care licenses/registrations
5. Loss of board certification
6. Exclusion from participation with Medicare, Medicaid, and other federal and state governmental programs
7. Commencement of other judicial or administrative proceedings (e.g., criminal proceedings, civil monetary proceedings, malpractice actions, and other state licensing actions)
8. Permanent reports to the National Practitioner Data Bank and state licensing data banks

Prior to the commencement of a formal hearing, there is often a window of opportunity in which an experienced and knowledgeable health care attorney can help the physician to develop and implement prophylactic measures and to take certain actions that may convince the licensing authorities not to proceed with disciplinary action or to accept a sanction less severe than originally recommended. Due to this relatively small time frame, it is imperative that the physician contact an attorney at the earliest recognizable stage of a potential licensing matter. As Benjamin Franklin once said: "an ounce of prevention is worth a pound of cure"—a physician that retains an experienced and knowledgeable health care attorney early in the process can often avoid the increased time and financial resources involved in trying to win a licensure case at an administrative hearing, when compared to resources needed to implement reasonable measures to rectify the alleged inappropriate behavior/conduct.

SETTING UP A PHYSICIAN PRACTICE

Introduction

Physicians very rarely graduate from medical school knowing how to successfully run a business. And a physician practice is just that: a business. Fortunately, physicians are often successful in organizing and operating their own medical practices, especially when they rely upon a team of qualified and experienced professionals, such as accountants, financial advisors, attorneys, billing companies, and third party payor enrollment consultants.

As discussed further below, from a corporate perspective, organization of a new business generally involves several steps, including each of the following:

a. Establishing the business entity (typically through a state-level filing of Articles of Incorporation, Certificates of Incorporation, Articles of Organization, or other equivalent document, as appropriate)
b. Applying to the Internal Revenue Service (IRS) for a federal tax identification number (EIN)
c. Protecting the name and other intellectual property of the practice, as appropriate
d. Negotiating and adopting governing documents (Bylaws, Shareholders' Agreement, Operating Agreement, Buy–Sell Agreement, etc.)
e. Adopting initial corporate resolutions to ratify the organization of the entity; adopting the governing documents; electing directors, managers, and officers, as the case may be; authorizing the establishment of a bank account; etc.
f. Enrolling in Medicare and other third party payors
g. Opening bank accounts and obtaining necessary insurance

Physicians who refrain from obtaining the valuable guidance of legal, financial, and reimbursement professionals in order to limit the associated costs often eventually incur unnecessary (and sometimes substantial) expenses to correct problems that would have been avoidable had the practice adopted a more conscientious approach to its organization. Examples of the unfortunate circumstances that sometimes face practices that have acted in an uninformed and/or careless manner include the following:

a. Failure to officially organize the business entity or provision of incorrect information when applying for an EIN, resulting in delay in receiving Medicare billing numbers and lost revenue
b. Disregard for corporate practice of medicine doctrines, if applicable, eventually requiring the practice to restructure
c. Misunderstanding of the nature of, and the benefits offered by, the form of business entity resulting in the physician entering agreements with hospitals and others in the physician's individual capacity instead of through the business, which can lead to unanticipated adverse tax consequences
d. Lack of appreciation for the importance of maintaining corporate formalities (such as holding annual meetings, adopting corporate resolutions, maintaining corporate records and minutes, etc.), which makes it more likely that creditors will attempt to impose personal liability upon the owners of an entity who otherwise have the protection of limited liability (often referred to as "piercing the corporate veil")

The purpose of this section is to provide a broad overview of certain considerations with respect to the organization of a new physician practice. As discussed above, it is highly advisable for physicians to engage professional advisors who are able to position the new practice for success. Nothing set forth below is a substitute for such guidance.

Choice and Formation of Business Entity

The form of a business entity, the relationship of such business entity to its owner(s) and creditors, and its operations are governed, at least in part, by the state in which the business is organized and the states in which the business operates.

Each state has its own specific statutes, regulations, and other guidance with respect to the various corporate forms recognized by such state. Most states publish an abundance of helpful information on their Web sites that explain the pros and cons of choosing one form of entity over another and the process for organizing such entity. State publications on these topics are often geared toward small businesses and include references to other related legal requirements, including those pertaining to taxes, licenses, and securities requirements. Although it is common for business entities to organize themselves in states other than those in which they operate (e.g., in the State of Delaware because of the favorable and well-developed corporate laws in such jurisdiction), physician practices are generally organized in the same state in which they operate

due to their relatively limited size and their heavily regulated nature.

A brief overview of certain common forms of business entities follow below. Although such descriptions are generally true, each state has its own unique requirements, and physicians should work with their legal and financial advisors with state-specific knowledge when making a final determination regarding choice of entity.

Sole Proprietorship

A sole proprietorship is a form of entity that is owned by one person who generally owns all of the assets of the business and is personally liable for the debts of the business. Because a sole proprietorship is not a business entity that is distinct from its owner, a sole proprietorship cannot continue beyond the life of the owner. Sole proprietorships generally do not need to file documents at the state level to form their business; however, they sometimes need to file their name and other information in the counties in which they operate. For the reasons just stated and others, it is rarely advisable for a physician to form a physician practice as a sole proprietorship.

Partnerships

Many states recognize at least two types of partnerships: (a) general partnerships and (b) limited partnerships.

General Partnerships

A general partnership is a form of entity that is owned by at least two people. All of the owners are personally liable for the debts of the business. All profits and losses of a partnership generally flow through to the partners for tax purposes. Partners often enter into a written partnership agreement to govern their relations. Typically no state-level filing is required to form a partnership, but partnerships sometimes need to file their name and other information in the counties in which they operate. Similar to sole proprietorships, it is typically inadvisable for a physician to form a physician practice as a partnership.

Limited Partnerships

A limited partnership is a form of entity that is owned by at least two people, at least one of which is a general partner who has personal liability for partnership debts and has the majority of management rights. Limited partnerships are typically distinct from general partnerships in that limited partnerships are generally created by filing documents at the state level and offer limited liability to some of its investors. Today, it is not common for physician practices to be formed as limited partnerships because of the lack of flexibility offered by most state limited partnership laws.

Nonprofit Corporation

Although rare, physician practices can be formed as nonprofit corporations, which are formed through state-level filings typically referred to as Articles of Incorporation. Depending upon the specific state law, nonprofit corporations may be formed on a stock, membership, or directorship basis for any lawful purpose not involving pecuniary gain or profit for its officers, directors, shareholders, or members. It is important to note that not all nonprofit corporations are federally tax-exempt organizations. Although many health care organizations are exempt from federal income tax under 501(a) of the Internal Revenue Code, such tax-exempt status is generally only available when all applicable requirements are satisfied and the entity submits an Application for Recognition of Exemption to the IRS.

Corporations

Profit corporations are generally formed by submitting a state-level filing for the purpose of generating profit for their owners, who are referred to as shareholders. The internal affairs of a corporation and the relationships among the shareholders are often governed by the corporation's Bylaws, Shareholders' Agreement, and Buy–Sell Agreement, as applicable. Such document filed with the state is usually referred to as the corporation's Articles of Incorporation or Certificate of Incorporation. Most corporations are governed by three layers of management: shareholders, directors, and officers. Shareholders, directors, and officers are generally not liable for the corporation's obligations unless they sign a personal guarantee or enter a contract in their individual capacity on behalf of the corporation. A corporation can exist indefinitely and its existence is not affected by the death of a shareholder. Except in the case of an S Corporation as described below, a corporation is taxed separate from its owners.

S Corporation

An S Corporation is a profit corporation that elects "S Corporation" status for federal tax purposes by filing Form 2553 (Election by a Small Business Corporation) with the IRS. S Corporations are distinct from other general profit corporations in that the profits and losses of the S Corporation flow through to the shareholders, who report the S Corporation's income and losses on their personal tax returns. There are several requirements that a corporation must satisfy in order to be eligible for S Corporation status, including, without limitation, the following: (a) be organized as a domestic corporation, (b) have only allowable shareholders (i.e., no partnerships, corporations, or nonresident alien shareholders as shareholders), (c) have no more than one hundred shareholders, and (d) have only one class of stock.

Limited Liability Company

Limited liability companies (LLCs) are created through state-level filings, which are generally referred to as an LLC's Articles of Organization. LLCs are sometimes managed by their owners, referred to as members. In other cases, LLCs are managed by a manager or group of managers (i.e., a Board of Managers), but the members continue to have ultimate authority over certain major decisions pertaining to the LLC. In addition to the Articles of Organization

or equivalent document, the internal affairs of a company and the relationships among the members are often governed by the company's Operating Agreement, as applicable. Members are generally not liable for the obligations of their LLC unless they sign a personal guarantee or enter a contract in their individual capacity on behalf of the company. For purposes of federal income tax, LLCs are taxed as sole proprietorships, partnerships, corporations, or S Corporations depending upon the number of members and the elections made by the LLC. An LLC can exist indefinitely and its existence is not affected by the death of a member.

Professional Service Entities

Many states either require or permit business entities that provide professional services such as medicine to be organized as a professional corporation, professional limited liability company, or other professional entity and be owned exclusively by licensed professionals who are legally authorized to provide such professional service. These requirements are typically set forth in the corporate statutory laws of such states.

Corporate Practice of Medicine

Many states prohibit a business entity from practicing medicine or employing a physician to provide medical services (often referred to as the "corporate practice of medicine") unless an exception applies. The state corporate practice of medicine prohibitions and exceptions is set forth in state statutes, regulations, case law, and attorney general opinions. Such prohibitions are intended to protect physician decision making and prevent a physician's loyalty from being divided between the needs of a corporation and the needs of the patient. States generally limit application of the corporate practice of medicine doctrine through certain exceptions, including those created for hospitals and other licensed health care facilities and also professional business entities such as professional corporations and professional LLCs. States often adopt these exceptions because the entities covered by the exception are either licensed themselves or owned by licensed physicians, and therefore, applying the corporate practice of medicine to such businesses is not necessary to advance the underlying purpose of the doctrine.

Name Protection

Physician practices, like most businesses, have an interest in protecting their identity and reputation. For those business entities that are formed through state-level filings, the applicable state will generally only accept the filing if the name of the business entity is distinguishable from other active names on the business records of the state. For many small physician practices, the level of protection offered by state corporate laws with respect to a corporate name is sufficient. However, business entity's that are more concerned about protecting their corporate names can register their name as a trade mark or service mark. Additional information regarding this process can be found at http://www.uspto.gov/smallbusiness/trademarks/.

Securing a Business Loan

Newly formed physician practices require capital to procure the resources required to commence operations (e.g., office space, office and medical equipment, IT/EHR software and hardware, furnishings, supplies, payroll, insurance premiums, legal and other professional expenses, etc.), and such capital may be obtained in several different ways. First, practice owners (usually referred to as the partners, members, or shareholders depending upon the form of business entity selected) often contribute capital or loan money to the business. Yet most physicians are unable to independently provide all of the necessary financing. Second, the initial financial burden of commencing the practice operations can be mitigated if the practice leases the items, or obtains financing from the vendor, instead of purchasing the items immediately in cash. Third, it is also important to note that federal law, including the federal Stark Law and Antikickback Law, permits hospitals to provide certain financial support and income guarantees to physicians that relocate and establish a practice within the geographic area served by a hospital when certain requirements are satisfied. Such support is most prevalent in underserved areas. Fourth, in the event that the options just described are insufficient, traditional third party financing is an attractive option. The legal and financial advisors to the practice often have strong relationships with banks and finance companies and can therefore recommend those that provide competitive interest rates on fair terms. However, it is important to understand that most lenders will require personal guarantees or other security interests necessary to sufficiently protect them if the practice defaults on the loan.

Securing Insurance

It is highly advisable for physician practices to acquire insurance coverage that is appropriate for the size and nature of the practice's business. Such insurance policies may include, without limitation, the following:

a. Commercial liability
b. Auto
c. Employment practices
d. Professional liability
e. Errors and omissions
f. Directors and officers
g. Premises liability
h. Personal property
i. Workers' compensation
j. Key-Man life
k. Health, disability, long-term care, etc.

Before contacting insurance agents to obtain information and quotes for coverage, physician practices should understand their insurance needs. For example, the practice should consider the following terms: coverage limits, naming additional insureds, whether the insurance should be on a claims-made or occurrence basis, who needs to be covered (i.e., employees, volunteers, etc.), etc. Practices also need to be cognizant of those insurance requirements imposed upon the practice by applicable state law (e.g., pertaining to workers' compensation insurance and often professional liability insurance) and those insurance requirements imposed upon the practice by contract (e.g., office space and equipment leases, employment and independent contractor agreements, agreements with hospitals, third party payors, etc.).

Obtaining a Federal Tax Identification Number

After a new business entity is officially organized (through the filing of Articles of Incorporation, Certificate of Incorporation, Articles of Organization, or otherwise), the next priority is generally to file for a federal employer identification number (often referred to as a TIN or an EIN). Additional information regarding federal tax identification numbers and the process for applying for such number can be found at http://www.irs.gov/businesses/small/. Irrespective of whether the application is submitted online, by telephone, by fax, or by mail, applicants must be very careful to complete the forms in a diligent manner to ensure that all information provided is complete and correct to avoid subsequent problems from arising. Physician practices should maintain a copy of the application and all related documentation, including IRS Form CP575 (which provides verification of the EIN), as it will often be required to open a bank account and apply for a Medicare provider number. Further, it is advisable for physician practices to work closely with their financial advisors in this regard to ensure that the S election, if applicable, and other related filings are timely filed.

Enrolling with Third Party Payors

In order for a physician practice to operate and thrive, it will be necessary for the practice to effectively and efficiently obtain reimbursement for its services. Therefore, enrollment with Medicare and other third party payors is an important part of organizing a physician practice. Today, Medicare enrollment can be accomplished electronically through CMS' Internet-based Provider Enrollment, Chain, and Ownership System established by the CMS, which is the branch of the U.S. Department of Health & Human Services (HHS) that administers the Medicare program. CMS Form 855B is the enrollment application used by clinics and group practices, and CMS Form 855I is the enrollment application used by physicians. Such applications require the submission of an abundance of information and documentation in a complete and accurate manner. Additional information pertaining to Medicare provider enrollment is available at http://www.cms.gov/MedicareProviderSupEnroll/. Each third party payor also has its own unique provider enrollment policies and procedures although many such payors utilize a universal credentialing application called Universal Provider Datasource, which is described at http://www.caqh.org/ucd.php.

IMPLEMENTING HIPAA PRIVACY AND SECURITY IN A PHYSICIAN'S OFFICE

Introduction

HIPAA, the Health Insurance Portability and Accountability Act,[29] was passed by Congress in 1996 and was designed to improve the efficiency and effectiveness of the health care system. Although the primary purpose of HIPAA is to protect health care coverage for individuals who lose or change their jobs, it also includes Title II, better known as the Administrative Simplification Act. Title II requires the U.S. Department of HHS to adopt national standards for electronic health care transactions in order for the health care industry to become more efficient. Congress also recognized, however, that advances in electronic technology could erode the privacy and security of health information. Consequently, Congress incorporated into HIPAA provisions that mandate the adoption of federal privacy and security protections for individually identifiable health information.

HIPAA Privacy Rule

The HIPAA Privacy Rule pertains to three categories of "covered entities"—health care providers, health plans,[30] and health care clearinghouses.[31] Health care providers are covered if they transmit health information electronically. Even a doctor in a small practice who keeps only paper records will almost certainly use a billing service that transmits information electronically. In short, it is nearly impossible to provide health care today without using electronic means in some way and therefore fall under the purview of the HIPAA Privacy Rule.

[29]Pub. L. 104–191.

[30]Health plan means almost anyone that pays for the cost of medical care. This includes health insurance companies, HMOs (health maintenance organizations), group health plans sponsored by an employer, Medicare and Medicaid, and virtually any other company or arrangement that pays for your health care.

[31]Health care clearinghouses can be any number of organizations that work as a go-between for health care providers and health plans. An example of this would be a billing service that takes information from a doctor and puts it into a standard coded format. Patients rarely deal directly with clearinghouses.

The HIPAA Privacy Rule generally safeguards the confidentiality of protected health information (PHI), which is defined as "individually identifiable health information" that is transmitted electronically, maintained electronically, or transmitted or maintained in any other form or medium.[32] It includes not only paper and electronic records but oral statements as well. Common documents that would be considered to contain PHI would include (a) all components of the medical record, (b) information contained on billing cards or superbills, (c) information contained on hospital face sheets, and (d) information contained on other forms such as the financial consent, informed consent, and patient information sheets.

The HIPAA Privacy Rule places restrictions on how a physician group can use PHI within the practice and how and when PHI can be disclosed to entities outside the practice. In general (with exceptions for emergencies), the privacy rule prohibits health care providers from using or disclosing PHI without first obtaining the patient's HIPAA consent. The HIPAA consent is different from informed and financial consents in that the HIPAA consent is for "use" and "disclosure" of PHI. However, HIPAA consent is not required to use and disclose PHI for treatment, payment, and operations.[33] If the physician group uses or discloses information for other purposes such as for certain research or marketing activities, a HIPAA authorization would have to be signed by the patient.

Another important document that must be provided to the patient at the time of the HIPAA consent is the group's HIPAA Notice of Privacy Practices.[34] This document is separate and apart from the HIPAA consent and must be posted in a conspicuous place in the physician's office. The HIPAA notice is a document that must set forth a number of items including, but not limited to, (a) all of the different uses and disclosures of PHI that the physician group is permitted to make under the privacy rule, (b) how the patients can get access to their information, (c) the manner in which patients can complain to the group with regard to potential breaches of privacy, (d) a statement that the patient has the right under HIPAA to request certain restrictions on their PHI (note that the group is not required to agree to all restrictions), and (e) an explanation of the privacy policies and procedures that the practice has put in place.

In addition to the HIPAA consent and notice requirements, physician groups are also required under the privacy rule to implement privacy policies, establish formal safeguards, and train the practice's staff to ensure the privacy of PHI. In order to meet these administrative requirements, organizations must first formally designate an individual within the organization as the "Privacy Officer." The Privacy Officer will be responsible for the "development and implementation" of the policies and procedures necessary for compliance under the HIPAA privacy rule.[35] These administrative requirements impose a focus on privacy that may have previously taken a back seat in the hectic, business-like atmosphere that often characterizes modern-day health care.

In order to effectuate the required training, physician practices should have compliance programs in place, which should include HIPAA education as part of an annual compliance education in service. The education should focus on providing employees with a general understanding of HIPAA as well as explaining the policies and forms that will be put in place. Education should also include practical tips to make certain that a patient's privacy is not breached, such as the following:

1. Following phone protocols. A medical office must have specific guidelines for what information is given over the phone. Certain individuals like health insurance representatives or family members might have clearance to be told patient information, but other callers should be given only basic information that does not violate HIPAA.
2. Protect workstations. A computer that has access to PHI, should always be locked when the person who uses it is away from the desk to prevent unauthorized use.
3. Protect papers. Documents like medical claims and bills should be turned face down when the person who is responsible for them is away from the desk. The files must be kept in secure containers where they cannot be read by someone passing by.
4. Use HIPAA-compliant waste baskets and shredders. Some offices have color-coded trash bins, one set for regular trash like apple cores and gum wrappers and another covered set of bins for documents. The documents that go in the secure bins get shredded every day. The other trash bins get emptied by cleaning people at night.

In addition to training its employees, practice groups must enter into agreements with each of their business associates (BAs) wherein the BAs agree to safeguard PHI provided by the group or PHI that the BAs access via permission of the group.[36] In general, BAs are independent entities that provide services on behalf of the group that involve PHI. A list of common BAs for a practice may include the following:

1. Billing companies
2. Practice management companies
3. Collection agencies
4. CPA firms and law firms

[32] 45 C.F.R. §160.103.

[33] The privacy rule incorporates what it calls a "minimum necessary" standard when it comes to how much information should be disclosed. Covered entities are required to limit the amount of information disclosed to others to the minimum necessary to accomplish the intended purpose. 45 CFR §§164.502(b), 164.514(d).

[34] 45 CFR §164.520(a) and (b).

[35] 45 CFR §164.530(a)(1).

[36] 45 CFR §§164.502€ & 164.504(e).

5. Independent compliance auditors
6. Record storage companies
7. Software vendors
8. Cleaning services

The HIPAA Security Rule

Privacy and data security go hand in hand. The security rule, like the privacy rule, creates a national standard. This means that all health care providers, health plans, and health care clearinghouses that transmit information electronically must adopt a data security plan.

Only PHI maintained or transmitted in electronic format (EPHI) is covered by the security rule.[37] For example, EPHI would include billing information contained on a computer system, electronic medical records, and computerized patient scheduling systems in an ENT practice. Although nonelectronic PHI (e.g., hardcopy medical charts) is not covered by the HIPAA security rules, this information is still protected by the HIPAA privacy rules.

The security rule, according to the HHS, was designed to be flexible, establishing a security framework for small practices as well as large institutions. All covered entities must have a written security plan.[38]

The general requirements of the HIPAA Security Rule mandate that covered entities do all of the following:

1. Ensure the confidentiality, integrity, and availability of all EPHI that the entity creates, receives, maintains, or transmits
2. Protect against any reasonably anticipated threats or hazards to the security or integrity of such information
3. Protect against any reasonably anticipated uses or disclosures of such information that are not permitted or required by the HIPAA Privacy Rule
4. Ensure workforce compliance[39]

To achieve compliance with the general HIPAA Security Rule requirements set forth above, covered entities are required to meet 18 standards. In order to meet each of these standards, the HIPAA Security Rule sets forth implementation specifications that serve as the instructions for compliance with each standard. There are two types of implementation specifications, "required" and "addressable."

Required implementation specifications must be implemented as set forth in the HIPAA Security Rule. Addressable implementation specifications allow covered entities to implement alternative specifications instead of, or in combination with, the implementation specification set forth in the HIPAA Security Rule. If an alternative approach is taken, the entity must document its decision not to implement the HIPAA Security Rule's implementation specification, the rationale behind its decision, and the alternative approach that it has chosen. The standards and their related implementation specifications are broken down into three broad categories: (a) administrative safeguards,[40] (b) physical safeguards,[41] and (c) technical safeguards.[42] The administrative safeguard standards require entities to analyze the risks of unauthorized disclosure of EPHI within the entity, implement a number of required policies and procedures, and maintain certain documentation to manage and minimize risk. Physical safeguard standards deal with the security measures taken to protect buildings and equipment, which house EPHI, from natural and environmental hazards and unauthorized intrusion. The policies and procedures required under this standard include policies to protect the physical locations that house electronic equipment, as well as to protect the equipment itself. Technical safeguard standards deal with the technologic measures to safeguard and control access to EPHI as well as the development and implementation of policies and procedures dealing with the use of technology.

To address HIPAA security, the following action plan should be implemented:

1. Appoint a Security Officer (this is required under the rule[43]) who must review and understand the requirements of the rule. The Security Officer may need to seek outside assistance from attorneys or consultants versed in the HIPAA Security Rule.
2. Identify BAs that are creating, receiving, or transmitting EPHI for the practice and include HIPAA security language in the BA agreement.
3. Inventory EPHI and electronic systems within the practice and begin working on the required policies and procedures.
4. Conduct required security training with all workforce members.

Why Physician Offices Must Be HIPAA Compliant

HIPAA sets a national standard for accessing and handling medical information. Before HIPAA, the right to privacy of health information varied from state to state. Now, health care providers, health plans, and other health care services that operate in all states have to abide by the minimum standards set by HIPAA. Any state is free to adopt laws that give patients more privacy, but it cannot take away the basic rights given by HIPAA.[44] Compliance with HIPAA's privacy and security requirements is mandatory, and failure to

[37] 45 CFR §160.103.
[38] 45 CFR §§164.306(b)(2) and (e).
[39] 45 CFR §164.306(a).
[40] 45 CFR §164.308(a).
[41] 45 CFR §164.301(a) to (d).
[42] 45 CFR §164.312(a), (b), (c), and (e).
[43] 45 CFR §164.308(a)(2).
[44] 45 CFR §§164.202, 164.203.

comply could lead to civil and criminal penalties. In 2009, the Health Information Technology for Economic and Clinical Health (HITECH) Act was passed, which, in part, strengthens HIPAA's privacy and security protections and, notably, increases its enforcement rules.

The HHS Office of Civil Rights (OCR), which in addition to its responsibility for enforcing the HIPAA Privacy Rule was given responsibility in July 2010 for security rule enforcement too, has implemented a stronger enforcement program in the form of HIPAA privacy and security audits. The OCR's implementation of proactive HIPAA compliance audits, required under the provisions of the HITECH Act, marked a shift from the largely reactive approach to compliance and enforcement seen since the HIPAA Privacy and Security Rules went into effect in 2003 and 2005, respectively. The audits will focus on how covered entities are meeting specific HIPAA requirements such as implementation of appropriate safeguards and seek evidence that risk analysis, contingency planning, and other key activities are in fact being carried out. In concert with stronger procedural methods for enforcement, the HITECH Act also increased the civil and criminal penalties for noncompliance, gave state attorneys general the right to sue covered entities for violations on behalf of state residents, and mandated formal investigations for any cases of HIPAA violations involving willful neglect. Collectively, all of these measures must make compliance a bigger priority for HIPAA-covered entities (and BAs too, since HITECH extended most HIPAA requirements to apply directly to them as well).

OPERATIONAL ISSUES

Office Electronic Medical Records

Electronic medical records lie at the center of any computerized health information system. However, there is no law that requires medical practices to adopt electronic records. Nonetheless, the HITECH stimulus act does threaten nonadopters with cuts in their Medicare reimbursements. The cuts begin in 2015 and increase to a maximum of 5% of the reimbursements. As such, while not a mandate or law requiring the adoption of electronic medical records, the HITECH Act strongly encourages physicians to do so.

One of the primary purposes of the HITECH Act and the regulations promulgated under HITECH is to promote use of electronic health records (EHRs) in a manner that advances quality, safety, and efficiency of patient care. To that end, the HITECH Act not only includes provisions to protect the privacy and security of patient health information contained within EHRs but also provides for significant financial incentives under Medicare and Medicaid to eligible health providers who demonstrate meaningful use of EHRs. HITECH specifically authorizes the CMS to provide reimbursement incentives for eligible professionals and eligible hospitals who are successful in becoming "meaningful users" of EHRs.

On July 13, 2010, CMS issued the Final Rule[45] titled "Medicare and Medicaid Programs; Electronic Health Record Incentive Program" (the "Final Rule"), which sets forth the criteria that eligible health providers must satisfy to demonstrate meaningful use of EHRs sufficient to receive incentive payments from the federal government.

Meaningful Use Criteria

Under the Final Rule, achieving meaningful use requires using certified EHR technology to achieve improvements in quality, safety, and efficiency in health care (i.e., physicians will not be able to achieve meaningful use through the adoption of EHRs alone). The Final Rule divides the meaningful use criteria into a "core" group of required objectives and a "menu set" of procedures from which providers can choose. This "two-track" approach ensures that the most basic elements of meaningful EHR use will be met by all providers qualifying for incentive payments while also allowing latitude in other areas to reflect the varying needs of providers pursuing full EHR use.

This Final Rule (Stage 1 of 3) will apply only to the first two (2) years of the federal meaningful use incentive programs. Stages 2 and 3 will include more stringent requirements for achieving meaningful use of EHRs in the future.[46]

Physician Eligibility

Eligible physicians, who for purposes of Medicare generally include doctors of medicine or osteopathy, dentists or dental surgeons, podiatrists, optometrists, and chiropractors, began registering for the EHR meaningful use Medicare/Medicaid incentive program in January 2011. Payments under the incentive program began in May 2011. Importantly, hospital-based physicians are not eligible for the Medicare incentive payments and, subject to certain limited exceptions, are also not eligible for the Medicaid incentive payments. Under the Final Rule, CMS defines hospital-based physicians as those who furnish at least 90% of their professional services within an inpatient hospital or an emergency room hospital. Typical examples of hospital-based physicians include pathologists, anesthesiologists, hospitalists, or emergency physicians. CMS will determine noneligibility based upon site of service codes. In other words, physicians providing services in outpatient settings, including ambulatory clinics, are eligible for incentives.

Some physicians believe that being exempt from eligibility for the Medicare/Medicaid EHR incentives is a desirable result. This is due to the fact that hospital-based physicians who are exempt from otherwise available incentives

[45]75 FR 44590.

[46]The requirements contained within each of the three stages have been hotly debated, most notably by the physician specialists. These specialists have repeatedly complained that the requirements are only realistically attainable by the primary care physicians, and as a result, they will face financial sanctions for being unable to meet unattainable goals in the meaningful use of EHR.

will also be exempt from the penalties that will begin in 2015 if a provider fails to meet the meaningful use requirements. According to many specialty groups, this is particularly significant since they will find it difficult to meet the meaningful use requirements because the measures either do not apply to their specialty or they are not reportable through their specific practice's information management systems.

Understanding Your Electronic Medical Record

As noted earlier in this chapter, physicians are facing unprecedented scrutiny in the submission of claims. For example, with respect to Medicare claims, not only do Medicare Affiliated Contractors (MACs), Medicare Carriers, and Intermediaries conduct their own audits, but also Medicare's RAC program is operational nationwide and has been expanded to include Part C and Part D claims, and Zone Program Integrity Auditors (ZPICs) and PSCs are conducting nationwide benefit integrity audits. With respect to Medicaid claims, MICs are actively auditing claims, and the RAC program is expanding to Medicaid claims as well. Physicians must be cognizant of this increased claims scrutiny and conduct themselves accordingly, with an increased focus on compliance.

Certain compliance issues are heightened with the use of electronic medical records. Auditors and medical reviewers routinely deny claims because an item or service is found not to be medically necessary. As such, it is essential that when a physician documents a service performed, such documentation must establish for the reviewer the medical necessity of the service rendered. There are special compliance issues that arise with respect to the use of electronic medical records, particularly with respect to issues of medical necessity. For example, many electronic medical records have built in "time savers," such as self-populating fields that insert a patient's medical history or procedural history into each record. These time-saving devices ultimately may hurt a provider if not used correctly, should the provider be subject to an audit. Auditors and claim reviewers may deny claims for medical necessity if it appears that the documentation is not tailored to the service performed but is merely a template. Each record should be distinct from the next. Additionally, auditors and claim reviewers may deny claims if they find that the medical records associated with the service or procedure are internally inconsistent. For example, claims have been denied because the medical record states in one area: "patient has no complaints of pain," but in another area states: "patient presents with severe pain." Providers using electronic medical records must ensure that they understand the capabilities of the software, have knowledge regarding which fields self-populate, and tailor each record to the patient's condition at the time of assessment.

With the coming of quality assessment programs from the government or commercial payers, the need exists for the inexpensive collection of quality data through a limited series of questions, typically less than 10. Independent of any externally mandated data collection effort you need to understand your practice and how you can better serve your patients. Several kinds of systems are available for use including the manual review of paper or electronic medical records, paper forms completed by the patient or staff, interactive voice response systems, local electronic data capture systems, or central web-based systems. The advantages and disadvantages of each system are beyond the scope of this chapter. Your chosen system should permit you to capture information easily into a readily accessible format (usually electronic) easily manipulated by you or your staff. Careful consideration should be given to the capacity of a practice through its EMR or other systems to acquire information in a cost-effective timely manner.

Use of the Shewhart cycle or PDCA (Plan, Do, Check, Act—repeat) has proven to be a useful tool for process improvement. Focus on the correction of issues preventable by process improvement. Identify the root cause (people, processes, tools, materials) of issues. The purpose of data acquisition is not to improve the outcome by measuring it, but to improve its production process. However, if the outcome is unknown or variable in its outcome, document the processes that produce the desired outcome. If the process is variable, the process must first be stabilized, and then measured against stakeholder expectations. As long as the process is unstable, it will be impossible to make systematic changes to the process and get uniform results. A stable production process will prevent errors and assure ongoing consistent quality outcomes. Often true medical outcomes are often too costly in time, effort, or money to measure, and interim process measures must be utilized. Picking an interim process step or outcome that has face validity maybe acceptable alternative. Whenever possible, identify and use standardized data definitions to facilitate comparisons with surrogate data.

Social Media and E-mail Communication

As with all businesses, medical practices face competition from other offices in their area and must differentiate themselves by portraying value and quality to their prospective clients. The use of social media outlets like Facebook, or collaboration tools like blogs or wikis, has provided a place for patients to learn about a physician's practice and decide on the value and quality of the practice before they become a patient. As a result, health care providers are more frequently utilizing social media to market their practices and to dispense health information. In doing so, however, it is critical for any provider or practice to ensure that their use of social media outlets does not inappropriately invade the physician–patient relationship or erode a continued positive Internet presence for health care providers.

With these goals in mind, the AMA adopted recommendations for physician use of social media.[47] The guidelines recommend that physicians utilize privacy settings on social media Web sites and develop appropriate mechanisms to monitor their Internet presence for accuracy and appropriateness. The AMA also suggests that health care providers maintain proper boundaries when interacting with patients on the Internet and exercise good faith efforts to protect their clients' privacy and confidentiality. Finally, the AMA cautions physicians to be mindful of the potential negative implications arising from the use of social media on their reputations and professional careers.

E-mail communication between physicians and patients within a professional relationship, in which the physician has taken responsibility for the patient's care, is also on the rise. Although the use of e-mail communication within this professional relationship can certainly be useful and effective, caution must be exercised when used for urgent matters or when relaying confidential information in that privacy and security measures are in place. Those patients who a provider communicates with via e-mail must have an understanding of the need to call the provider's office directly if the matter is urgent (requiring a response on the same day) and have a clear understanding of the expected response time on nonurgent e-mails. This can best be accomplished by written statements on all e-mail communications with patients that clearly states the relevant expectations and understandings.

The AMA has also issued guidelines governing the use of e-mail within the physician–patient relationship.[48] Within these guidelines, the AMA urges against the use of e-mail communications as replacing "the crucial interpersonal contacts that are the very basis of the patient-physician relationship" but that it only be used to enhance such contacts.

Hospital Call

A physician's duty to undertake hospital emergency department call and whether or not the hospital is required to pay for such call coverage (and if so, how much) is a complicated and evolving matter with vast ethical, legal, and medical implications. Typically, hospitals require physicians within certain specialties to share in some minimal amount of emergency department call coverage in order for the hospitals to meet certain federal and state quality of care requirements (e.g., EMTALA) and therefore mandate that these physicians provide some minimal call coverage in order to obtain and maintain medical staff privileges at the hospitals. However, over the years, in certain geographic areas, there has been a reduction in the willingness of physicians to provide such coverage, in part, due to an increase in the number of uninsured patients receiving their only care in emergency rooms, a shortage of certain specialty physicians, falling reimbursement for certain specialty physician services, and a perceived increase in the risk of lawsuits to the physician if the physician provides such coverage. In August 1992, the OIG published a report on Specialty Coverage in Hospital Emergency Departments, which found that "sixty-seven percent of hospitals report that they encounter difficulty ensuring coverage for at least one specialty service they offer in their emergency departments." The report also indicated that only about 10% of the hospitals encouraged specialty physicians to provide emergency care by offering them direct compensation for being on the on-call list. At the time, the OIG strongly encouraged physicians, hospital administrators and boards, consumers and advocacy groups, health insurers, and government officials to get together and address the issue immediately. Unfortunately, approximately 20 years later, we are still faced with the same issues.

When physicians request compensation for providing the additional emergency department call coverage requested by the hospital in order to offset the physicians' aforementioned financial concerns, legal issues arise. Such compensation may run afoul of numerous federal and state laws governing hospital–physician relationships including, but not limited to, the federal AKS and Stark regulations. Moreover, nonprofit hospitals also need to be aware of IRS regulations pertaining to private inurement and benefit issues to maintain their nonprofit status. The remainder of this article focuses on how such compensation may run afoul of the federal AKS.

The OIG has expressed concern that payments by hospitals for ER call coverage could be easily misused to entice physicians to join or remain on the hospital's staff or to generate additional business for the hospital in violation of the AKS. While the AKS bars the parties from making unlawful kickback payments in any form, it does not compel physicians to provide on-call services for free. As with any compensation relationship between a hospital and a physician, compensation for ER call coverage must be at fair market value for actual and necessary services rendered based upon an arm's length transaction and cannot take into account, directly or indirectly, the value or volume of any past or future referrals or other business between the parties. On-call compensation will be scrutinized to ensure that it is not a vehicle to disguise improper payments for referrals. Although the OIG does not opine on whether a certain dollar amount is or is not at fair market value *per se*, it has published two instructive advisory opinions that should guide physicians and hospitals when deciding an appropriate on-call compensation arrangement.

On September 20, 2007, the OIG issued Advisory Opinion 07-10, which provides some guidance as to how

[47]AMA Policy: Professionalism in the Use of Social Media. www.ama-assn.org/ama/pub/meeting/professionalism-social-media_print.html
[48]AMA H-478.997 Guidelines for Patient-Physician Electronic Mail

to structure such compensation arrangements to avoid AKS violations. Included in the Advisory Opinion were statements by the OIG that warned against on-call compensation arrangements: (a) based upon lost opportunity (i.e., payments that do not reflect bona fide/actual lost income to the physician), (b) where physicians are compensated and there are no identifiable services provided, (c) involving aggregate payments that are disproportionately high compared to the physician's regular practice income, and (d) wherein the physician receives separate reimbursement from insurers or patients in addition to the hospital's on-call payment resulting in the physician being paid twice for the same services. The OIG approved the per diem payment arrangement to physicians who were willing to (a) participate in an equal prorate share of on-call coverage, (b) provide follow-up inpatient care, (c) timely respond to calls, (d) appropriately document the services provided, (e) participate in quality programs, and (f) provide 1.5 days of uncompensated on-call coverage per month. The per diem rate was based upon (a) the physician's specialty, (b) the severity of the illness typically seen by that specialty, (c) the likelihood of having to respond to call or provide follow-up care, and (d) whether the coverage was on a weekday or weekend (which resulted in a slightly higher fee).

On May 14, 2009, the OIG issued Advisory Opinion 09-05, which provided some additional guidance on how to structure an AKS-compliant on-call compensation arrangement. The OIG approved an alleged FMV flat fee-for-service arrangement where, in order to be reimbursed for claims provided to indigent and uninsured patients treated at the hospital's ER, the physicians were required to (a) participate in an on-call rotation, (b) provide follow-up inpatient care, (c) timely respond to calls, and (d) evaluate the patient in person. The flat fee schedule was determined based upon patient acuity levels, average length of stay, physician time commitment for each kind of service, and consideration of the fees paid by public, private, and self-payors for such services.

On October 23, 2012, the OIG issued Advisory Opinion 12-15, to address an inquiry regarding a hospital's payment of per diem fees to physicians for providing on-call coverage for unassigned patients presenting to the hospital's ER. The hospital's arrangement involved 130 specialist physicians who provide unrestricted call coverage for the ER per written agreement whereby they agree to respond within a required time frame, provide inpatient care and follow-up care in their office practices for ER patients whom they admit, timely prepare medical records, and participate in medical staff committee appointments—all regardless of an ER patient's insurance status or ability to pay. The hospital created an uniform per diem fee to be paid to the physicians providing such call in each specialty based upon numerous factors associated with each specialty's call burden including the number of days per month that a specialist would likely be called, the number of patients likely to be seen per call day, and the number of patients likely to require inpatient and follow-up care. The hospital retained an independent consultant who opined that the per diem rate was consistent with fair market value without regard to the volume or value of referrals or any individual physician's referral pattern. The OIG warned against arrangements that pay for "lost opportunity" (as opposed to true lost income), which pay more than FMV, or which pay physicians for services for which they already receive separate reimbursement. Nonetheless, the OIG approved the arrangement based upon similar factors set forth within Advisory Opinions 07-10 and 09-05 including that the per diem payments: (a) were consistent with fair market value and tailored to reflect the call coverage burden applicable to each specialty; (b) were calculated and allocated in advance each year without regard to physician referral patterns; (c) were the only payment available to the physicians for a significant amount of care provided; (d) were offered to all specialists in staff required to provide unrestricted call coverage under the hospital's bylaws; and (e) did not result in any additional costs to the federal health healthcare programs.

With the increasing desire to have specialists on call at hospitals, there will likely be more guidance issued in the future to address such matters.

HIGHLIGHTS

- The business of medicine is complex. Obtain key advisors and specialists to assist you in the management of your practice.
- Ultimately, you, the physician, are responsible for your provider number. You need to be familiar with the billing rules.
- Bad results do not in and of themselves result in a potential malpractice risk. Communication breakdowns are often at the heart of many malpractice actions.
- Malpractice claims require four basic elements: establishing the medical provider had a duty of care, that the duty was breached by conduct not in accordance with a standard of care, that the breech was the cause of the injury, and the plaintiff suffered damages.
- The discovery phase is the nuts and bolts of the litigation process. In it the physician learns the exact nature of the charges being advanced and the steps necessary to defend the claim. Preparation is paramount as few cases are won during the discovery but many more are lost.
- Settlement of a malpractice action may be the best course of action based upon the jurisdiction, judge, attorney, physician factors, convenience, merit, or an emotional standpoint.

- Two professional liability insurance policies are available: occurrence and claims made. The former offers protection from losses that occur while the policy is in effect. Claims-made policies offer protection from claims made during a specific time period. Upon termination, tail coverage is often necessary with a claims-made policy.
- Protection of your personal assets is a top priority. Professional liability insurance, the use of IRAs or employee benefit plans, life insurance, and the services of an experienced estate planner, accountant, or tax expert may be a few of the strategies used to protect personal assets.
- Empiric evidence tying malpractice and tort reform to medical malpractice litigation is limited and provides little support for the contention that it is the most effective means of managing skyrocketing malpractice premium rates or reducing health care costs. Further defensive medicine is motivated by more than fear of litigation.
- The Physician Self-Referral Law, commonly referred to as the Stark Law, prohibits a physician (or immediate family member) from making referrals of DHS such as laboratory services, DME, home health, hospital services, radiology and other imaging services, PT, OT and speech services, and radiation therapy for Medicaid or Medicare patients to an entity they have a financial relationship with without an exception. Proof of specific intent to violate the law is not required.
- The Antikickback Statute makes it a crime to knowingly and willfully offer, pay, solicit, or receive any remuneration (anything of value) for referral of items or services reimbursable by a federal health care program.
- Physicians need to develop and maintain systems in their practice to oversee coding, billing, and documentation for services rendered. Physicians should steer clear of any situation in which their decision making with respect of patient referrals or use of products is based upon anything other than what is medically necessary and appropriate.
- The seven components of a compliance program include conducting internal monitoring and auditing, implementing compliance standards, having a compliance officer or designate, conducting education and training, responding in a timely and appropriate fashion to detached offenses and developing corrective action plans, keeping communication avenues open with patients and staff, and enforcing disciplinary standards.
- Licensure actions arise out of complaints and should prompt appropriate counsel and response at the earliest possible stage.
- Organizing a practice has seven basic steps: establishing the business entity, obtaining an IRS federal tax identification number, protecting the name and any intellectual property, developing the governing documents of the business, adopting the necessary corporate resolutions to ratify the business entity, enrolling in third party insurance plans, and opening business accounts and obtaining the necessary insurance.
- The HIPAA safeguards the confidentiality of PHI that is transmitted electronically. Virtually every practice is covered by this act even if you chose not to use an electronic medical record.
- Compliance issues related to medical necessity are highlighted when documentation in the electronic medical records is not tailored to the service performed but is merely a template.

Compliant Documentation, Coding, and Billing in the Practice of Otolaryngology—Head and Neck Surgery

200

Stephen R. Levinson

How many physicians look forward to learning about documentation and coding? Probably as few as the number of businessmen who want to learn the details of the tax code. Yet documentation and coding are as integral to the practice of medicine as accurate bookkeeping and correctly filing taxes are to anyone operating a business. From their earliest exposure to performing history and physical examinations, medical students who have great teachers are admonished that their documented medical record for each patient encounter should be an accurate and understandable reflection of the medical care they provided and the thought process they followed. (As summarized by the great medical record innovator Dr. Lawrence Weed, "It's not sufficient to just know what was done. It's a very incomplete record if we don't know why it was done" (1). What is, however, seldom appreciated and rarely taught is that the use of creatively designed medical record documentation tools can improve quality, compliance, and efficiency for recording diagnostic and surgical procedures and especially for documenting and coding evaluation and management (E/M) care. When used for documenting E/M services, effective medical record tools also increase workflow efficiency and promote physicians' diagnostic patient care process. The benefits of effective documentation further extend to include audit compliance, medicolegal protection, communication with other physicians, and, most importantly, helping to ensure optimal patient care for both current and future visits.

While physicians almost universally understand the role that coding plays in filing claims for insurance, they must also appreciate its role in data retrieval and information processing. In the office setting, diagnostic and procedure codes are the gateway to accessing the records of patients who have undergone specific procedures or who have been diagnosed with particular illnesses. Accurate coding facilitates chart review and analysis of the success of various treatment options, as well as initiating patient recalls under appropriate circumstances. These individual practice benefits are magnified by combining related data from large numbers of physician practices, facilitating "comparative effectiveness research" (CER), which is one of the promised benefits of widespread use of electronic health records (EHRs). The requirement for coding correctly has been underscored by the proliferation of coding and health information management (HIM) professionals, who in various settings may be employed to review, assist, or even replace coding by physicians. However, even if their hospital or practice employs coding professionals, physicians need to understand coding fundamentals to achieve correct codification of patient care and to ensure receiving proper payments for their services.

SURVEYING THE CURRENT ENVIRONMENT AND SEARCHING FOR SOLUTIONS

Why do physicians so frequently complain that the tasks of creating consistently compliant (2) documentation and coding are confusing, challenging, and/or unrelated to their goals for medical practice? It is far easier to learn how to identify the precise procedure and diagnostic codes for excision of a benign neoplasm of the lateral lobe of a parotid gland with dissection and preservation of the facial nerve (CPT code 42145 and ICD-9 code 201.2) than it is to master the surgical technique required to perform that challenging operation safely and well. Similarly, with a relatively small amount of training combined with compliantly designed (and physician-friendly) medical record forms, it is far easier to perform and document the medically indicated level of care for a new patient with probable Meniere's disease (CPT code 99204 and ICD-9 code 386.01) than it is to master the optimal evaluation and management pathways for each patient who presents with significant vertigo.

This author believes there are three factors creating barriers to logically and naturally incorporating precise documentation and accurate coding into optimal medical workflow and patient care excellence:

- Lack of early training in coding principles and their integration into medical care
- Lack of efficient and compliant documentation tools that can enable physicians to create documentation at the level and precision that is taught and required
- Lack of teaching physician and practicing physician role models who excel in compliant documentation and coding

All three of these deficiencies could, and should, be remedied by introducing effective curricula and documentation tools at the appropriate junctures during medical education. For example, effective *documentation* of a comprehensive history and physical examination (the "H&P") is traditionally taught as the first medical school course in clinical medicine, and this meaningful clinical documentation almost exactly parallels the compliant H&P required for evaluation and management (E/M) documentation and coding. This would be an optimal time to introduce sophisticated documentation tools to help young physicians provide and document the desired level of care compliantly. Use of such tools would also allow students to achieve good care far more efficiently than the "time-honored" approach of documenting with only a blank sheet of paper and a pen. As almost all physicians have experienced, performing and documenting a comprehensive H&P with such primitive technology requires between 45 and 90 minutes per patient encounter; this is the medical record equivalent of training students to examine the tympanic membrane using nothing more advanced than direct vision with an open ear speculum or to auscultate the heart by placing their ear directly against the patient's chest.

The demands of our current medical environment require practicing physicians, academic physicians, residents, and even medical students to complete patient encounters within 10 to 20 minutes. Unfortunately, failure to provide sophisticated documentation tools that facilitate performing and documenting extensive care within this time frame has forced student physicians (and now their professional supervisors and role models) to abandon the high-quality history taking and physical examination they were taught to perform. As a consequence, most physicians currently provide and record only "problem-focused" patient care, which creates compliance problems for their evaluation and management services. The current transformation to EHRs offers a welcome window of opportunity to provide such tools, but unfortunately most current EHR data entry designs have failed to facilitate the recording of *individualized* (patient-specific and visit-specific) documentation that "meet all of the optimal standards that physicians should apply to introduction of any medical record technology… usability, efficiency, E/M compliance, promotion of individualized quality care, and data integrity" (3).

Linking the Quality History and Physical Examination with E/M Documentation and Coding

Since the mid-1970s, probably the most commonly used reference text for teaching medical students the principles of obtaining and documenting a high-quality history and physical examination is the Bates' "Guide to Physical Examination and History Taking" (4). Revealingly, comparing both the E/M section of the AMA publication "Current Procedural Terminology" (5) (CPT) and the American Medical Association (AMA)/Centers for Medicare and Medicaid Services (CMS) publication "Documentation Guidelines" (6) with the Bates' Guide text of clinical practice makes it apparent that "this reference book is unquestionably the source of the E/M coding system. The descriptions of medical history and physical examination match concept for concept, paragraph for paragraph, and often almost word-for-word among the three documents. This includes not only the broad concepts, but also the details such as the various organ systems listed in the review of systems and physical examination and the specific definitions for chief complaint (CC) and history of present illness. It also includes a similar overview of formulating and documenting clinical assessments and treatment plans. Most impressively, the Bates' Guide also presents the concept of the 'nature of the patient's problem.' This component of patient assessment parallels CPT's similarly named E/M component 'nature of the presenting problem' (NPP), which plays a pivotal role … in helping physicians understand how an effective E/M system promotes excellence in patient care.

In summary, the E/M coding system is actually a codification of the medical diagnostic process that all physicians learn in their training as being the most effective method for providing high-quality patient care. Making physicians aware of this relationship allows them to view compliance-based records from a fresh perspective: rather than being an added chore at the conclusion of patient care, carefully designed IMR *(Intelligent Medical Record)* tools can help physicians comfortably provide optimal care within a time frame that meets the limitations of the current health care environment" (7).

In the optimal documentation and coding model presented here, medical students would receive medical record tools and instruction that together facilitate their ability to provide the comprehensive (and compliant) H&P taught during their early clinical training. This monitoring and mentoring of patient care and *documentation* should continue throughout residency training as well. In addition, it appears reasonable and logical that, at the onset of residency training, effective and compliant *documentation* templates should be introduced for recording diagnostic and therapeutic procedures, helping residents develop, practice,

and thereby maintain effective procedure documentation techniques from the outset.

Finally, the beginning of residency training would also be an optimal time to introduce the fundamental concepts of *coding* for procedures (CPT coding) and diagnoses (ICD-9 coding, soon-to-be replaced by ICD-10 coding). These alphanumeric codes provide a shorthand "language" for recording and reporting the care physicians provide. Just as early childhood is the most successful learning time frame for introducing an individual to a new language, incorporating coding as a parallel language early in residency will enable young physicians to speak this language fluently.

Unfortunately, our medical training programs do not currently provide this idealized approach to incorporating effective documentation and coding skills and tools as an integral component of learning medical care excellence. Instead, upon completing residency training, most physicians are plunged unprepared into the chilling waters of creating documentation that must meet regulatory demands for coding and billing, performance measures, medicolegal protection, and compliance reviews. This current reality calls for an explanation of documentation and coding that can make these principles understandable and workable for practicing and academic physicians, for residents, and even for medical students.

The remainder of this chapter is devoted to presenting the basic principles of each component of coding and documentation and examining their interplay with the current payment system in the United States. This includes examples of structured documentation tools capable of incorporating these principles into the normal workflow of quality patient care, and it underscores the basic tenet that proper coding and documentation must accurately *report* the care provided, not *distort* that care to meet external regulatory demands.

DOCUMENTATION FUNDAMENTALS

Hippocrates probably documented his patient care by writing freehand on parchment with a quill pen. As his patient volume increased with his widening fame, he probably began to experience the time limitations of creating accurate records using such limited technology. Yet over the next several thousand years, the only significant technologic advances for improving medical documentation were the introduction of milled paper and the ballpoint pen. With mounting time pressures, many physicians increased their writing speed by becoming less and less legible, some even attaining a level of illegibility that left them unable to read their own notes. A significant alternative for recording care finally appeared in the 20th century in the form of dictation. This offered physicians an option that was definitely legible and could also be faster than writing an entire record in longhand. In addition, however, it added the often-significant cost of transcribing the dictated records into paper documents.

Whether created by handwriting or dictation, the final medical records were stored as paper documents, which have inherent limitations in ease of access and costs of storing, retrieving, and sharing the records, as well as mining them for data. The heralded introduction of EHRs offers solutions to these information storage and retrieval problems, but it has also introduced a broad spectrum of challenges to effective data entry. Early on, physicians adopting EHRs were required to type their medical observations into the software programs, a process that is not only usually slower than either dictation or writing but also creates barriers to good patient–physician interaction (or alternatively leads to the double effort of physicians writing notes to themselves on paper, which they then use to type their notes at the end of the day, long after seeing their patients; this is a suboptimal and perhaps noncompliant solution to the data entry challenge). Eventually, some electronic records introduced full or partial dictation alternatives, but many have also introduced a variety of automated data entry shortcuts by copying and pasting blocks of text from previous records and/or from preloaded generic descriptions. While speeding the process of documenting a patient encounter, these shortcuts severely curtail *individualized* documentation, introducing significant problems with compliance (8–10) and challenges in understanding what was actually performed (and why it was performed) during each encounter. Fortunately, effective data entry solutions are achievable, and these are also able to provide documentation that is accurate, individualized, and efficient. Physicians should therefore establish criteria that the data entry features of EHR systems must meet to ensure usability, efficiency, compliance, data integrity, and promoting quality care.

Toolkit for Designing Medical Records to Meet Physicians' Needs

There are several medical record documentation tools that can help physicians create records that surpass the standard written or dictated format. These include

1. **Choice of interface** (graphic and narrative): Traditional medical record documentation required that all information be entered as free text. This approach necessitates a time commitment that is unreasonably excessive to meet today's medical care demands.
   a. **Narrative interface**: There remains a critical requirement for free-text narrative descriptions for those portions of a medical procedure or visit that call for analog (expository) documentation (e.g., an individualized history of the patient's present illness during a visit for evaluation and management care).
   b. **Graphic interface**: A preprinted list of questions or descriptions from which to select appropriate responses using check boxes or similar indicators (e.g., a survey of possible medical illnesses in the past

medical history section of the H&P screen or form). A more sophisticated variation expands this option by also allowing the entry of brief written details along with positive responses to the preentered questions.

2. **Use of preloaded information** (templates and macros): Criteria for proper medical record design for documentation of procedures and, particularly, of evaluation and management services must carefully distinguish between *template* designs that facilitate efficiently recording *individualized* care and *macro* designs that automatically enter identical clinical information in visit after visit and case after case (a process that is labeled "cloned documentation"). While these features have become pervasive in many EHRs, some physicians have incorporated templates or macros into their written or dictated paper records, where they have similar advantages and potential dangers.
   a. **Template**: A preloaded graphic interface section that provides detailed structure but no substance until active documentation is entered
      i. An effective office template should list all the elements of a comprehensive ENT physical examination with blank check boxes after each element to indicate either "normal" or "abnormal" findings. The physician checks the appropriate finding for each area examined and leaves blank those boxes for exam elements not performed during a particular patient encounter (all abnormal findings are further described with supplemental narrative detail).
      ii. In other words, until a physician *documents* his or her actual findings, the paper form or electronic screen shows only a blank template of information. There is NO preloaded documentation that anything has yet been performed.
      iii. Well-designed templates provide similar advantages for documentation of PFSH (past history, family history, social history) and Review of Systems obtained during initial E/M visits.
   b. **Macro**: A preloaded graphic interface section that provides detailed structure plus standardized substance, because all of the check boxes have been prefilled to indicate normal findings (alternatively, in EHRs, a template form may be converted to a macro when a single electronic "click" *automatically* checks all of the normal boxes). In its narrative form, a macro's preloaded information presents as one or more completed descriptive paragraphs that appear identical to a dictated normal head and neck examination (or a completely negative background history and review of systems).
      i. In other words, before the physician even meets the patient, the macro-loaded paper form or electronic screen attest that he or she has performed a comprehensive head and neck examination and the findings were 100% normal.
      ii. Hypothetically, such macros require "documentation by exception"; that is, the physician is supposed to undocument all exam elements that were not performed and to re-document all exam elements that were found to be abnormal. If done correctly, this undocumentation and re-documentation process, though compliant, actually requires more time and effort than individually checking the blank boxes of a template. It is also subject to multiple oversights that can result in erroneous documentation. In practice, few physicians expend the effort to re-document their macros. As a result, even when physicians using macros perform a limited or focused examination, their records commonly report a comprehensive examination for every visit, almost always with all normal findings except for the one or two areas related to the patient's presenting problem.
      iii. Unless a physician meticulously reviews each item of a macro and undocuments and re-documents each element that was not normal (or negative), the use of macros inevitably results in "cloned documentation." (A recent analysis from the Department of Biomedical Informatics at Columbia University reported that EHRs using macros created medical records where 54% of the wording was identical on progress notes and 78% was identical on discharge notes (11).)
      iv. The use of macros in creating medical documentation will usually fail to support a physician under the scrutiny of a compliance audit, as noted below, or a medicolegal inquiry. Clinically, unless extensively modified line-by-line, macros also fail to convey meaningful patient-specific and visit-specific information needed to assist the physician in the ongoing care of his or her patients.

The Compliance Verdict on "Cloned" Medical Record Documentation

Over many years, CMS and various Medicare Carriers have released a series of critiques of "cloned" medical records, that is, records created by various macro techniques such as "copy forward" (of information from a patient's previous visits), "copy/paste" (of preloaded generic history or examination descriptions), and/or documentation by exception. In 2007, First Coast Service Options, the Florida Medicare carrier, issued a persuasive condemnation of these documentation techniques:

> "Cloned documentation does not meet medical necessity requirements for coverage of services rendered due to the lack of specific, individual information. All

> documentation in the medical record must be specific to the patient and her/his situation at the time of the encounter. Cloning of documentation is considered a misrepresentation of the medical necessity requirement for coverage of services. Identification of this type of documentation will lead to denial of services for lack of medical necessity and recoupment of all overpayments made" (12).

The compliance (and potential financial) danger of improperly employing these data entry techniques was further underscored in a white paper issued in 2007 by the Department of Health and Human Services (HHS) and the Office of the National Coordinator for Health Information Technology (ONCHIT). Their assessment uses the term "templates" to indicate the characteristics of "macros" as described above:

> "These tools include the use of defaults, templates (i.e., *macros*), copying, and others. These are legitimate benefits of using an automated system and can be extremely helpful if used correctly; however, the tools can also open the EHR-S up to fraud or abuse" (13).

v. For E/M services, it is clear that macros should not be used for documenting any portions of the medical history or physical examination. On the other hand, the "correct use" cited above would permit macros to be used effectively and compliantly in portions of the medical decision-making E/M component, to import standard lists of diagnostic tests and/or treatment programs for specific diagnoses. However, such use still requires review for appropriateness and individualized customization during each encounter, prior to incorporating a macro into the medical record.

vi. Similarly, it appears that macros should have only carefully controlled use in operative reports, permissible only for standard manipulations and only if there is additional individualized narrative information describing the key portions of the diagnostic or therapeutic procedures.

3. **Optimal use of *data entry personnel***: Although all documentation of the medical history and physical examination has traditionally been entered by the physician (as instructed in medical school), the 1995 and 1997 editions of the *Documentation Guidelines* provide two far less time-consuming alternatives for obtaining and documenting multiple subcomponents of the medical history. They instruct, "The ROS (*Review of Systems*) and/or PFSH (*Past History, Family History, and Social History*) may be recorded by ancillary staff or on a form completed by the patient" (14). This guidance is highly logical, because each physician employs his or her own standard set of questions for each of these medical history elements. Permitting patients to review and respond to these inquiries is extraordinarily efficient. It allows physicians to elicit and record a *comprehensive* medical history without significant time expenditure. Further, the information obtained promotes quality care by providing full background information, identifying both contributory and unrelated medical issues. These insights allow physicians to accurately determine a preliminary differential diagnosis and a preliminary assessment of the nature of the patient's problem ("NPP"—the E/M coding system's measure of *medical necessity*).

Of course, medically it is insufficient just to obtain and document this medical history information; the physician must also review the responses and further investigate all positive findings (i.e., it is not sufficient to simply record that a patient has chest pain—the physician must inquire about the details to determine whether this symptom may be medically significant, potentially health endangering, and/or require assessment). The *Documentation Guidelines* reflects this quality care mandate by requiring "to document that the physician reviewed the information, there must be a notation supplementing or confirming the information recorded by others" (14) (note: clearly the advice to "supplement" refers to all positive responses, while "confirm"—with an attestation by signature—is appropriate to indicate review of all the negative responses).

4. **Optimal use of appropriate *data entry modalities***: Effective documentation requires the use of data entry tools that facilitate the efficient entry of individualized and accurate medical information. In the traditional paper environment, physicians elect to write or dictate their documentation. Prior to the introduction of EHRs, few, if any, physicians chose to record the H&P by typing, either during the care process or as an additional step following each encounter. The process would be too time-consuming and/or too intrusive into the physician–patient interaction.

Considering these drawbacks, it is remarkable that numerous EHR software systems have chosen to require the use of keyboard and mouse as the primary or only technology available for physicians to document their care. Therefore, to meet the usability, efficiency, and patient interaction requirements of all physicians, it should be required that EHRs provide at least one alternative for each data entry option

a. For physicians who prefer direct computer entry, use of keyboard and mouse
b. For physicians who prefer to dictate some or all of their records, use of (i) voice recognition software or (ii) dictation with transcription
c. For physicians who prefer to write (legibly) some or all of their records, use of (i) a tablet PC or (ii) a digital pen with digital paper

In addition to physicians' personal preferences, each of these technologies offers its own particular advantages and limitations (15). Often overlooked is the potential added efficiency and usability of combining two or more of these modalities, each being employed where it is most comfortable for the physician. For example, a physician with poor handwriting might elect to use a tablet PC or mouse entry with clicks to rapidly place Xs in the check boxes of the graphic interface section of the physical examination (see Fig. 200.7) while dictating the free-text narrative required to precisely describe the details of each of the abnormal findings.

CODING AND BILLING FUNDAMENTALS

Whereas the principles and practice of physicians accurately *documenting* their patient care have been evolving since Hippocrates saw his first patient, the concept of "codifying" that patient care is a relatively recent phenomenon. It was not until the 1980s that Medicare and most insurers began requiring that physicians submit their claims for payment using CPT procedure codes and ICD diagnostic codes. Prior to that time, physicians submitted most insurance forms with a free-text description of the procedure performed (e.g., "tonsillectomy and adenoidectomy") and the accompanying diagnosis (e.g., "chronic tonsillitis"). Following the transition to payments based on coding, the purpose of which "is to provide a uniform language that will accurately describe medical, surgical, and diagnostic services" (16), practices have been required to select the most appropriate CPT procedure code (e.g., 42820, for tonsillectomy and adenoidectomy, younger than age 12) and the most appropriate ICD diagnosis code (e.g., 474.02, for chronic tonsillitis and adenoiditis).

Resources for Compliant Coding and Documentation (publications are available through various medical and compliance organizations)

1. CPT: Current Procedural Terminology" (*procedure codes, including E/M codes*)
2. "CPT Assistant" (*periodical, which publishes explanations and clarifications of CPT codes and instructions*)
3. "International Classification of Diseases, ICD-9-CM" (*diagnosis codes*)
4. "HCPCS Level 2" (*additional procedure codes*)
5. "Documentation Guidelines for Evaluation and Management Services," 1995 and 1997 editions (*Evaluation and Management Documentation principles*)
6. "Medicare RBRVS: The Physicians' Guide" (*Medicare RVUs and payments, global periods, assistant at surgery restrictions, cosurgeon adjustments*)
7. "CPT Reference of Clinical Examples" (AMA scenarios for correct coding of procedures and E/M services)
8. "National Correct Coding Initiative (NCCI) Edits" (Medicare scenarios for correct coding of procedures)

Resources for Compliance in Otolaryngology—Head and Neck Surgery (Available through the American Academy of Otolaryngology—Head and Neck Surgery)

2. AAO-HNS Policy Statements: http://www.entnet.org/Practice/policystatements.cfm
3. AAO-HNS Clinical Practice Guidelines and Clinical Consensus Statements: http://www.entnet.org/Practice/clinicalPracticeguidelines.cfm

Although physician practices and hospitals view procedure and diagnosis coding almost exclusively through the lens of its role in reporting claims for proper payment, these codes also play additional roles in improving health care. CPT advises that its procedure code functions extend to "the development of guidelines for medical care review… to medical education and outcomes, health services, and quality research by providing a useful basis for local, regional, and national utilization comparisons" (16). ICD-9-CM codes are a United States "clinical modification" of the World Health Organization's International Classification of Disease. Its published intent is "to serve as a useful tool to classify morbidity data for indexing medical records, medical care review, and ambulatory and other medical care programs, as well as for basic health statistics" (17). These functions provide the foundation for some of the goals for system-wide use of EHRs, which are intended to facilitate the collection of coded information about symptoms and diseases, including the relative success of various procedures used to diagnose and treat them.

While these coding benefits promise to advance medical science and improve population health, the primary impact of coding on practicing U.S. physicians is accurate submission of claims to obtain correct payment in a timely manner. Reliable coding for payment depends on accurate documentation, and these demands will increase with the greater coding specificity being introduced in 2014 with the transition to ICD-10 diagnostic codes.

Integrating Coding and Billing Principles into Documentation and Patient Care

Commonly underemphasized or even overlooked in discussions of coding and billing practices, the critical factors in achieving compliant coding and documentation are *specificity* and *medical necessity*.

Specificity

Specificity is a central feature in identification of correct *procedure codes*, E/M codes, and diagnosis codes. CPT, the guide for procedure codes, instructs physicians to

> "Select the name of the procedure or service that *accurately identifies* the service performed. Do not select a CPT code that merely approximates the service provided. If no such specific code exists, then report the service using the appropriate unlisted procedure or service code. In surgery, it may be an operation; in medicine, a diagnostic or therapeutic procedure; in radiology, a radiograph… Any service or procedure should be *adequately documented* in the medical record" (18).

These instructions not only underscore the need for specificity in identifying correct codes, they highlight the direct compliance link between coding and documentation. Physicians must have an appreciation and understanding of procedure codes in order to ensure that their *documentation* supports (i.e., verifies) that the procedure being coded was, in fact, performed. The potential hazards of nonspecific documentation and noncompliant coding are emphasized below.

Specificity is similarly a central feature in identification of correct *diagnosis codes*. ICD-9, the current guide for *diagnosis* codes, instructs physicians to

> "Describe the patient's condition using terminology that uses **specific** diagnoses as well as symptoms, problems or reasons for the encounter. If symptoms are present but a definitive diagnosis has not been determined, code the symptoms… Determine whether the code is at the highest level of ***specificity***. Assign three digit codes (category codes) if there are no four-digit codes within the code category. Assign four-digit codes (subcategory codes) if there are no five-digit codes for that category. Assign five-digit codes (fifth digit subclassification codes) for those categories where they are available" (19).

Medical Necessity

Medical necessity introduces the concepts of "standards of care" and, more recently, "evidence-based medicine" (EBM) into correct billing practices. Physicians are comfortable considering the *medical indications* for ordering tests, diagnostic procedures, medical treatments, and therapeutic procedures. ***Medical necessity*** is the parallel terminology used as a prime determinant for appropriate payment in insurance reviews. (This concept may also carry considerable weight in evaluations of quality care or professional liability.) Physicians commonly assume that their personal decision to provide various levels of office care, perform diagnostic or therapeutic procedures, or order certain diagnostic tests automatically qualify as a certification of medical necessity. In response to concerns about some of these decisions, Medicare and private insurers elected to establish and apply their own standards of medical necessity, at times using them as a basis for denying payment for correctly coded services. The resultant conflicts, appeals, and failure to have a common understanding of this concept between physicians and insurers became one of the pivotal issues in the national class action lawsuits filed by physician organizations against health insurers in the first decade of the 21st century (20). The negotiations on this issue prompted the AMA and its affiliated specialty organizations to promulgate a definition of medical necessity that, with modifications during the negotiations, has become an established standard applied by physicians and insurers alike:

> "'Medically Necessary' or 'Medical Necessity' shall mean health care services that a physician, exercising prudent clinical judgment, would provide to a patient for the purpose of preventing, evaluating, diagnosing or treating an illness, injury, disease or its symptoms, and that are: (a) in accordance with generally accepted standards of medical practice; (b) clinically appropriate, in terms of type, frequency, extent, site and duration, and considered effective for the patient's illness, injury or disease; and (c) not primarily for the convenience of the patient, physician, or other health care provider, and not more costly than an alternative service or sequence of services at least as likely to produce equivalent therapeutic or diagnostic results as to the diagnosis or treatment of that patient's illness, injury or disease. For these purposes, "generally accepted standards of medical practice" means standards that are based on credible scientific evidence published in peer-reviewed medical literature generally recognized by the *relevant* medical community, Physician Specialty Society recommendations and the views of physicians practicing in *relevant* clinical areas, and any other *relevant* factors" (21).

The introduction of the word "relevant" in multiple portions of this definition addressed concerns in broad language commonly found in insurer contracts that gave carriers wide latitude to consider any factors they chose. (Note: This definition's compromise language concerning *relative cost* of alternative services raises concerns about patients' rights to choose their care, even if more costly, under the doctrine of informed consent. While this notion could raise issues between patients and their insurers, physicians must be aware of the potential for insurers to deny payment for more costly service options; under such circumstances, it is advisable that they seek approval for payment prior to initiating such care.)

Fundamental Precepts of Billing, Coding, and Documentation

Three fundamental principles of medical record auditing provide the insight physicians need to understand correct billing and coding and to conceptualize their requirements for properly designed documentation tools needed to facilitate compliant coding while promoting optimal patient care:

1. Medicare stipulates, "***Medical necessity*** of a service is the overarching criterion for payment in addition to the individual requirements of a CPT code" (22).
   a. This statement reflects criteria in section 1862 of Social Security Law that stipulate, "no payment may be made under (*Medicare*) part A or part B for any expenses incurred for items or services which… are not ***reasonable and necessary*** for the diagnosis or treatment of illness or injury or to improve the functioning of a malformed body member" (23).
   b. Finally, in its section reviewing payment for E/M services, the Trailblazer MAC's website further clarifies, "Federal law requires that ***all expenses*** paid by Medicare, including expenses for Evaluation and Management (E/M) services, are '***medically reasonable and necessary***'… Medicare's ***determination of medical necessity is separate*** from its determination that the E/M service was rendered as billed… At audit, Medicare will deny or downcode E/M services that, in its judgment, ***exceed the patient's documented needs***" (24).
2. "If medical care is not documented in the medical record, it is treated as if it had not been performed." (25)
   a. Although this statement is no longer found in the current CMS Carriers' Manual, it was obtained from section 7103.1(i) of an older version. Related language also appears on the Trailblazer MAC website, reporting that an error in coding occurs when "Documentation is incomplete/insufficient: (*i.e.,*) documentation does not support the level of service billed" (26).
3. "Automation is not documentation" (27).
   a. Preloaded generic clinical information that is copied and inserted from previous encounters (copy forward), from preloaded macros (copy/paste) or created by filling in multiple check boxes with a single click (documentation by exception) fail to record individualized clinical information related to each patient and each encounter. Although the use of automated data entry is most frequently found in suboptimal designs for EHRs, similar functionality has found its way into dictated operative reports and E/M records with distressingly increasing frequency.
   b. Reviewing records created with automated documentation reveals that physicians using this approach almost always undocument and redocument only the clinical information that is relevant to their patient's presenting illness. Because of the automated defaults to "normal findings," all other aspects of the patient's health almost always appear in the completed H&P as normal—a circumstance that is not compatible with the reality of most patients' health status. In other words, such "cloned records" attempt to give the impression that the physician performed *comprehensive care*, when in fact the repetitive "normal" findings in history and examination related to other organ systems attest to the fact that the physician performed and accurately documented only *problem-focused care*.
   c. As noted above in the box reporting a "final verdict" on cloned documentation, automated documentation consistently fails to provide both of the critical factors needed for compliant coding and documentation: it is insufficient to record the ***specificity*** required for individualized clinical information, and it is therefore "considered a misrepresentation of the ***medical necessity*** requirement for coverage of services" (28).

Fortunately, these three auditing principles can be transformed into three powerful core documentation principles that physicians can employ to ensure compliant documentation, coding, and billing:

1. When (patient-specific and visit-specific) care is documented, it was done.
2. When care is medically necessary, and that necessity is ***documented*** in the medical record, payment must be made.
3. Nonautomated (i.e., individually documented) records promote compliance and can also enhance quality of care.

DESIGNING MEDICAL RECORDS TO MEET PHYSICIANS' NEEDS

These three documentation principles can be used as cornerstones for medical record designs that meet all of physicians' requirements for effective documentation and coding tools:

- Usability: Ease of data entry with options to use multiple data entry modalities—dictation, legible handwriting, and/or keyboard and mouse
- Efficiency: Completing care and individualized documentation in a reasonable time frame without sacrificing compliance or data integrity
- Compliance: For both procedure and E/M records, the documentation should verify specific details of what was performed and the medical necessity of performing that care.
- Data integrity: The documented record should clearly and easily convey all the care performed and the reasons why it was performed (to another physician, to a reviewer, and most importantly to the physician himself/herself during subsequent visits).
- Promoting quality patient care: During E/M services, compliance-based documentation tools follow the diagnostic paradigm taught to physicians from the Bates' Guide; this facilitates providing levels of care warranted by the NPPs during each encounter.
- Appropriate productivity: Care, documentation, coding, and billing are all achieved at medically indicated levels, which the physician determines and sets based on his or her assessment of medical necessity.

Compliant Designs for Documenting Operative Procedures

While surgeons have been dictating operative reports for many years, the traditional approach commonly includes only demographic information, preoperative and postoperative diagnoses, the name(s) of the operation(s) performed, and a free-text narrative of the procedure. However, the operative note frequently fails to provide an explanation of the medical indications (i.e., the ***medical necessity***) for performing the procedure. More recently, some physicians have also sought to save time in creating their operative reports by instructing their transcriptionists to insert generic macros to describe the procedure performed, in lieu of individualized dictation. This effort to save dictation time and costs illustrates the danger of replacing documentation with automation: every operation for every patient reads almost exactly the same, thereby sacrificing ***specificity***.

These deficits can be remedied. ***Medical necessity*** should be documented by adding a section for "indications" near the beginning of the report. Here the physician dictates a narrative description of the clinical rationale warranting the performance of the surgical procedure. ***Specificity*** for the significant observations made during the course of the operation should be documented by dictating individualized narrative descriptions of the steps in the procedure and insertion of an additional section labeled "Operative Findings." This section conveys the nuances of the operation and significant anatomic findings and challenges. For example, when dictating a tonsillectomy, the surgeon can document whether significant scar tissue or aberrant blood vessels were found in the dissection plane of each of the two tonsils, as well as the approximate amount of bleeding and how readily it was controlled. Figure 200.1 illustrates a sample template for operative procedures, including sections to document indications and operative findings.

Can macros ever be used compliantly in an operative report? Only under stringent guidelines. Most surgeons employ a reasonably standard technique when performing the straightforward procedures of tonsillectomy and adenoidectomy (T&A) or myringotomy with tube insertion. A physician could employ a detailed macro that reports this standardized procedure, providing that the physician adds specificity by dictating individualized narrative sections for "Indications" and "Operative Findings." In addition, if a particular procedure presents unusual challenges, difficulties, and/or complications, the procedure section should be documented individually instead of attempting to modify the macro. For more extensive operations that have greater complexity and/or variation in anatomic and pathologic findings, it is preferable for specificity that physicians avoid macros and dictate the procedures as free text.

Similar principles apply to creating compliant templates for minor diagnostic procedures performed in the office setting, such as fiberoptic laryngoscopy, fiberoptic nasal endoscopy, and fiberoptic nasopharyngoscopy. Because examination of the larynx, pharynx, and nasal passages are included elements of the physical examination portion of E/M visits in the practice of Otolaryngology—Head and Neck Surgery, there must be appropriate medical indications documented to warrant billing for these services in addition to the usual direct and indirect (mirror) examinations of the internal nose, pharynx, and larynx.

Patient Name: _____

Date of Operation: _____/_____/_____

Operation(s) Performed: _____

_____

Surgeon: _____

Pre-Operative Diagnoses: _____

Post-Operative Diagnoses: _____

Indications:

Operative Findings:

Procedure:

Figure 200.1 Sample operative report for operating room procedures.

A user-friendly, efficient, and compliant operative report template, as illustrated below, can include

- A graphic interface for rapid documentation of the appropriate medical indication(s)
- A brief macro describing the standard topical anesthesia, passage of the endoscope, and areas examined
- A section for documenting specific operative findings that combines graphic elements to record normal findings plus narrative sections (indicated by blank lines) to record details of all significant or abnormal findings

For physicians who prefer to dictate (or whose handwriting is illegible), the same template can be used with only the free-text sections being dictated instead of writing on the blank lines. When the operative report thereby becomes a hybrid of written template plus dictation, it is preferable to check the box labeled "see attached dictation" to ensure that the record is not misinterpreted in the case of an audit or medicolegal review.

Below are sample templates of operative reports for fiberoptic laryngoscopy and diagnostic nasal endoscopy (Fig. 200.2).

Patient: _____ Account #: _____

Date of Operation: _____ / _____ / _____ ☐ **With Video Review**

Surgeon: ☐ Dr. A ☐ Dr. B ☐ Dr. C ☐ Dr. D

Procedure: **Flexible Fiberoptic Flexible Pharyngo-Laryngoscopy**

Pre-operative Diagnosis: _____

Post-operative Diagnosis: _____

Indications for use of fiberoptic examination: Need for improved visualization due to:

☐ Hyperactive gag reflex ☐ Posterior epiglottis position

☐ Obstructive base of tongue ☐ Inability to visualize anterior commissure

☐ Detailed evaluation of lesion ☐ History of treated neoplasm

☐ Enhanced mucosal visualization (to evaluate inflammation and edema)

☐ Evaluation of documented obstructive sleep apnea, with Mueller maneuver

☐ Other: _____

Procedure: The patient's nose was prepared with topical anesthesia, using cotton pledgets moistened with a solution of 4% lidocaine combined with 0.5% neosynephrine. Five minutes was allowed for anesthetic and vasoconstrictive effect, and the pledgets were removed. A flexible fiberoptic laryngoscope was advanced through the nostril to sequentially examine the nasopharynx, palate, oropharynx, base of tongue, epiglottis, larynx, hypopharynx, and piriform sinuses.

Findings:

Nasopharynx:

☐ Normal mucosa ☐ Diffuse inflammation: mild moderate severe

Larynx and hypopharynx:

Vocal cords: ☐ normal ☐ abnormal Arytenoids: ☐ normal ☐ abnormal

Retrocricoid: ☐ normal ☐ abnormal Post commiss: ☐ normal ☐ abnormal

Palate and oropharynx/Other:

_____ ☐ See attached dictation

Signature

Figure 200.2 Sample procedure reports for diagnostic nasopharyngolaryngoscopy and nasal endoscopy.

Patient: _____ Account #: _____

Date of Operation: _____ / _____ / _____ ☐ **With Video Review**

Surgeon: ☐ Dr. A ☐ Dr. B ☐ Dr. C ☐ Dr. D

Procedure: **Diagnostic Fiberoptic Nasal Endoscopy**

Pre-operative Diagnosis: _____

Post-operative Diagnosis: _____

Indications for use of fiberoptic examination: Need for improved visualization of intranasal anatomy, due to:

☐ Assess chronic sinusitis (post Rx)
☐ Assess nasal polyp(s) (post Rx)
☐ Chronic headache/facial pain
☐ Uncontrolled posterior epistaxis
☐ Need to visualize ostiomeatal complex
☐ Need to visualize posterior nasal space
☐ Need to evaluate compression points
☐ Need to visualize nasopharynx
☐ Pre-operative planning for endoscopic sinus surgery
☐ Other: _____

Procedure: The patient's nose was prepared with topical anesthesia, using cotton pledgets moistened with a solution of 4% lidocaine combined with 0.5% neosynephrine. Five minutes was allowed for anesthetic and vasoconstrictive effect, and the pledgets were removed. The rigid fiberoptic nasal endoscope was advanced through each nostril in turn to sequentially examine the septum, turbinates, ostiomeatal complex, and nasopharynx.

Findings:

Right nostril:
Mucosa: ☐ normal ☐ inflamed ☐ edematous
Septum: ☐ normal ☐ abnormal
Ostiomeatal complex: ☐ normal ☐ abnormal
Mucus: ☐ normal ☐ abnormal
Turbinates: ☐ normal ☐ abnormal
Nasopharynx: ☐ normal ☐ abnormal

Left nostril:
Mucosa: ☐ normal ☐ inflamed ☐ edematous
Septum: ☐ normal ☐ abnormal
Ostiomeatal complex: ☐ normal ☐ abnormal
Mucus: ☐ normal ☐ abnormal
Turbinates: ☐ normal ☐ abnormal
Nasopharynx: ☐ normal ☐ abnormal

Figure 200.2 *(Continued)*

Compliant Designs for Documenting Evaluation and Management (E/M) Services

The E/M documentation and coding system first appeared in the 1992 edition of the AMA's publications of CPT. It is built on the economic principles of the resource-based relative value system (RBRVS), also introduced in 1992, which for each service provided (and coded) seeks to quantify the relative values of physicians' individual work, practice expense, and liability insurance costs. Early E/M training focused almost exclusively on the system's three "key components": medical history, physical examination, and medical decision-making. These are the E/M elements used to report the ***specificity*** of care provided. However, as E/M training evolved, compliance experts recognized the importance of placing equal emphasis on NPPs, which is one of the E/M system's four contributory factors. "[A] critical insight to coordinating coding and documentation

with ***medical necessity*** and appropriate quality care is to include NPP as a mandatory fourth factor" (29).

Performing and documenting effective evaluation and management services has received steadily increasing emphasis over the last several years through recent initiatives for (a) implementation of quality measures; (b) MS-DRG requirements for sophisticated reporting of hospital inpatient E/M services; (c) adoption of EHRs; (d) increasing oversight through audits by Medicare Administrative Contractors (MACs), the Office of the Inspector General (OIG), Recovery Audit Contractors (RACs), and the new Zone Program Integrity Contractors (ZPICs); and (e) continued economic constriction (relative to practice costs) in the Medicare and insurer payment systems.

"As physicians and administrators confront the challenges created by these and other changes in the health care environment, they consistently discover that meaningful solutions depend upon effective, compliant, and efficient medical record documentation. Meeting this goal begins with documentation of a meaningful history and physical examination (H&P), which helps physicians ensure that their patients receive levels of clinical care that are appropriately matched to the severity of their illnesses (i.e., matched to the nature of the presenting problems)" (30). Although a comprehensive analysis and presentation of complete solutions to the E/M compliance challenge are beyond the scope of a single chapter, reviewing a set of core principles can provide the basis for incorporating reliable and compliant E/M documentation and coding into patient care. In addition to the three core documentation principles cited previously, effective E/M methodology and documentation tools can be built on a foundation of five basic postulates:

1. *Quality care must be the principle measure for effective medical records*. This principle puts documentation and coding into proper perspective; patient care comes first, and rules and guidelines must conform to this framework to be considered credible.
2. *The E/M process must "work" for clinicians*. That is, the protocol for evaluating patients must be compatible with physicians' optimal diagnostic process and patient care workflow. Since the E/M system is a codification of the workflow presented in the *Bates' Guide to Physical Examination and History Taking*, incorporating E/M guidelines into the structure of a medical record form results in a document that is familiar to physicians (the comprehensive H&P learned in medical school) and intuitive for them to learn and use.
3. *Medical record forms must incorporate consideration and documentation of the NPPs*. This inclusion provides documentation of medical necessity, based on the physician's case-specific assessment. It also allows the forms to include compliant documentation prompts, which can guide physicians to perform, document, and code for medically indicated levels of care that are warranted by the severity of patients' illnesses.
4. *Appropriate documentation and coding must be integrated into the process of providing care*, not added on as an additional challenging task at the end of a patient visit.
5. *Use of tools, not rules*. Successful medical record designs incorporate all E/M requirements and guidelines into sophisticated documentation ***tools***, instead of demanding physicians to memorize long lists of complex compliance rules.

Effective *E/M methodology* reflects the ideal care process and workflow that physicians are taught during their training. Unfortunately, the demand for completing this care in a limited time frame prevents physicians from implementing this optimal workflow due to lack of appropriate documentation tools. Providing effective and efficient tools, as described below, gives physicians the ability to reapply the optimal diagnostic process. This process begins with a comprehensive medical history (complete PFSH and review of systems plus an extended history of present illness) during every patient visit. This global review of each patient's status not only facilitates developing an accurate and inclusive differential diagnosis; it also provides the perspective physicians need to determine the relative severity of illness (i.e., the NPPs). Armed with this insight, plus helpful documentation prompts on their H&P templates, physicians can then perform and document the appropriate level of physical examination and medical decision making that are medically indicated by the severity of the NPP. Of course, while history-based severity assessments are frequently accurate, they are confirmed or modified on the basis of findings during the physical examination and review of available diagnostic tests.

Precise documentation of *all* E/M elements is critical to ensuring E/M compliance, particularly in the event of an external audit. This includes documentation of the traditional H&P components: (a) complete medical history, (b) normal and abnormal examination findings, (c) data reviewed, (d) assessment (differential diagnosis), and (e) plans (treatments and data ordered). However, two critical elements required for E/M compliance should be added to this standard approach: (f) documentation of the physician's assessment of the three levels of risk and (g) documentation of the physician's final assessment of the NPPs. The three levels of risk are described in CPT and the Documentation Guidelines Table of Risk (31) as

> "The risk of significant complications, morbidity, and/or mortality, as well as comorbidities, associated with (1) the patient's presenting problem(s), (2) the diagnostic procedure(s), and/or (3) the possible management options" (32).

The additional documentation of a physician's assessment of levels of risk and the NPP can be accomplished efficiently through the use of check boxes on the H&P form, and this supplemental documentation provides irrefutable support for the ***medical necessity*** of the level of care provided.

Effective *H&P forms* should be designed for usability and efficiency, with inclusion of E/M compliance rules to ensure appropriate care and documentation. Figures 200.3 to 200.9 illustrate portions of E/M forms for outpatient services (appropriately modified forms can be designed for inpatient care or other E/M services as well). These templates are compatible with the specialty of Otolaryngology—Head and Neck Surgery, including the single organ system ENT examination from the 1997 Documentation Guidelines.

Physicians at Teaching Hospits and "Physician Presence"

On December 13, 1995, The New York Times published a report that sent a compliance shock wave through the community of academic physicians. It reported that the "University of Pennsylvania's Health System has agreed to pay thirty million dollars to settle government complaints that it filed improper Medicare bills for doctors' services.... This substantial settlement followed a Government audit of one hundred patients treated in 1993" (45). The government had extrapolated the outcome of this limited audit over all of the comparable records for multiple years, calculating a fine that was significantly higher than the final settlement amount.

The audit identified two significant issues. One concerned submission of claims for E/M services at levels significantly exceeding the level of care documented in the medical record by residents and physicians (the same E/M issues discussed above). The second issue highlighted a new concept that subsequently became known as "physician presence." Charges had been submitted by attending physicians for E/M services that were clearly provided and documented by residents. Although physicians had placed their signature on the residents' charts, there was no documented evidence of the attending physicians being present during the residents' care of the patients or of independently performing any of the billed patient care. Instead, the audits determined that the teaching physicians' signatures on the charts indicated only they had reviewed the resident's notes, not that they had provided actual E/M services. The audit concluded that this practice was evidence of billing twice for the same service, since Medicare pays an additional fee to teaching hospitals for the residents' care of covered patients, and that was the only care documented as having been performed.

In establishing requirements for teaching physician to submit E/M claims when caring for patients in conjunction with residents, Medicare and the OIG referred to established rules published by the Health Care Financing Administration (HCFA; now CMS) in Intermediary Letter 372 (IL-372). HCFA subsequently clarified these guidelines in 1996 in a new "Final Rule for Teaching Physicians," presented in section 15016 of the Medicare Carriers Manual. In 2002s Transmittal 1780, CMS augmented section 15016 with several clarifications and examples for writing attestations of care, though without substantially altering the established principles and documentation requirements for teaching physicians to submit E/M claims. It is noteworthy that adhering to these more recent shortcut suggestions frequently leads once again to imprecise documentation of the actual care that teaching physicians perform. It can therefore be advised that incorporating the actual details of IL-372 and section 15016 into templates to document physician presence provides superior guidance and increased probability of compliance.

Teaching physicians are cautioned that if they elect to simply sign residents' notes, they should not submit claims for these services. However, following such an approach would not only be inadequate to meet payment requirements, it would also fail to reflect care provided, fulfillment of resident teaching responsibilities, and protection in the event of a professional liability claim.

On the positive side, the IL-372 and section 15016 guidelines provide three scenarios that permit attending physicians to submit claims for E/M services when they share care with residents. In the first scenario, the teaching physician would personally perform, document, and code only for the elements of an E/M service that he or she completed independent of the resident (46); this approach requires more time for comprehensive care and documentation than optimal in the teaching situation. In the second option, the resident performs the elements required for an E/M service in the presence of, or jointly with, the teaching physician, and the resident documents the service (47); except under unusual circumstances, this approach also requires excess teaching physician time and creates awkward scheduling challenges.

The final compliant option fortunately matches up extremely well with appropriate patient care workflow for teaching physicians. In this approach, the resident provides and documents the level of care medically indicated for the patient, and "the teaching physician independently performs the critical or key portion(s) of the service with or without the resident present and, as appropriate, discusses the case with the resident. In this instance, the teaching physician must document that he or she personally saw the patient, personally performed critical or key portions of the service, and participated in the management of the patient. The teaching physician's note should reference the resident's note. For payment, the composite of the teaching physician's entry and the resident's entry together

must support the medical necessity of the billed service and the level of the service billed by the teaching physician" (47). This third scenario allows teaching physicians to see their patients independently, where they can review their residents' "comprehensive" medical notes and then perform and document care that is "problem focused" on the patients' major medical issues. This also allows for the common practice where attending physicians regularly communicate with and teach their residents about these issues during normal teaching rounds. There are two requirements for effective documentation tools for teaching physicians to achieve compliant documentation and coding in this setting. First, the resident requires compliant documentation tools such as those described above (appropriate forms for inpatient care are available (48)) to ensure that his or her care and medical record documentation support the appropriate level of service. The resident's H&P record should also report the name of the attending physician. Second, the teaching physician will benefit from a compliant medical record template built on the principles and vocabulary of IL-372 and CMS section 15016 guidelines. A sample form is shown in Figure 200.10.

CODING COMPLEXITIES, RBRVS, AND USE OF MODIFIERS

Excellent documentation and correct coding of each procedure or E/M service are essential for compliance and for billing, but they are only the first steps towards successful submission of claims for payment to MACs and private insurers. These fiscal organizations use sophisticated software systems with complex paradigms of coding relationships to determine the circumstances under which they will authorize payments for your claims.

Figure 200.7 Initial outpatient visit—physical examination (41). This section is based on the single organ system examination for "ear, nose, mouth, and throat" presented in the 1997 Documentation Guidelines. Physicians must document findings for all elements examined as normal or abnormal. Pertinent normal descriptions are preloaded, and physicians must provide detailed descriptions for all abnormal findings (42) (by writing on the blank lines or by supplemental dictation). Note the documentation prompt, based on medically indicated level of care, located at the bottom of the section.

Claims for Individual Services Only

The most straightforward of these paradigms certify that procedures are age and gender appropriate and cross-check databases to ensure that charges are not made for surgery on body parts that had previously been removed. For example, a claim for CPT code 99385 (initial preventive medicine evaluation, age 18 to 39 years) will be rejected if the insurer's records indicate the patient is only 13 years old. Similarly, claims will be rejected for a prostate biopsy on a female patient or for gallbladder surgery on a patient whose records document previous performance of a cholecystectomy.

On a more sophisticated level, payers' claims processing software compares for appropriateness each procedure code with the associated diagnosis code(s). It will automatically reject procedure code 31575 (fiberoptic laryngoscopy) if it is submitted with diagnosis code 470 (deviated nasal septum); the diagnosis does not support medical necessity for performing this type of procedure. Most of these software programs also assign an assumed level of illness severity to various diagnosis codes as well as medical necessity indicators for many pairings of procedure and diagnosis codes. As a result, for example, the programs will generally deny claims for E/M code 99214 (moderate to high NPP) when submitted with the sole diagnosis code of 460 (acute nasopharyngitis or common cold) or 461.2 (acute ethmoid sinusitis); these diagnoses are not usually associated with sufficient illness severity to warrant high-level E/M services. They will also reject claims for CPT code 31231 (diagnostic nasal endoscopy) if submitted with either code 460 or

Also note the documentation prompts, based on medically indicated level of care, located in each subsection.

461.2 because of lack of medical necessity (medical indications) for performing this procedure under these circumstances. It is therefore essential for physicians and/or their staff (billing specialists or certified coders) to match each CPT code with one or more appropriate diagnosis codes. In addition, many accounts receivable systems for medical practices are equipped with "claims scrubbers," software programs that review the coding and identify potential coding discrepancies for review and possible correction prior to claim submission.

Claims for Multiple Procedures on Same Date of Service

The magnitude of coding and billing challenges increases significantly when claims are submitted for two or more procedures, or for a procedure and an E/M service, performed on the same date of service. Addressing the complexity of claims for multiple CPT services requires an appreciation of a number of fundamental coding and billing principles.

Principle #1: The claims processing software of Medicare Carriers and essentially all private insurers are programmed to authorize payment for only one service per day. (The exceptions to this policy are codes labeled as "add-on codes" and codes with an "XXX" designation, indicating they are exempt from being combined under a surgical package or global concept.) Achieving payment for more than one appropriately coded service on the same day requires the use of appropriate *modifiers* to alert payers' software that the claims should be paid. Modifiers are described in detail in Appendix A of CPT (49) and summarized below.

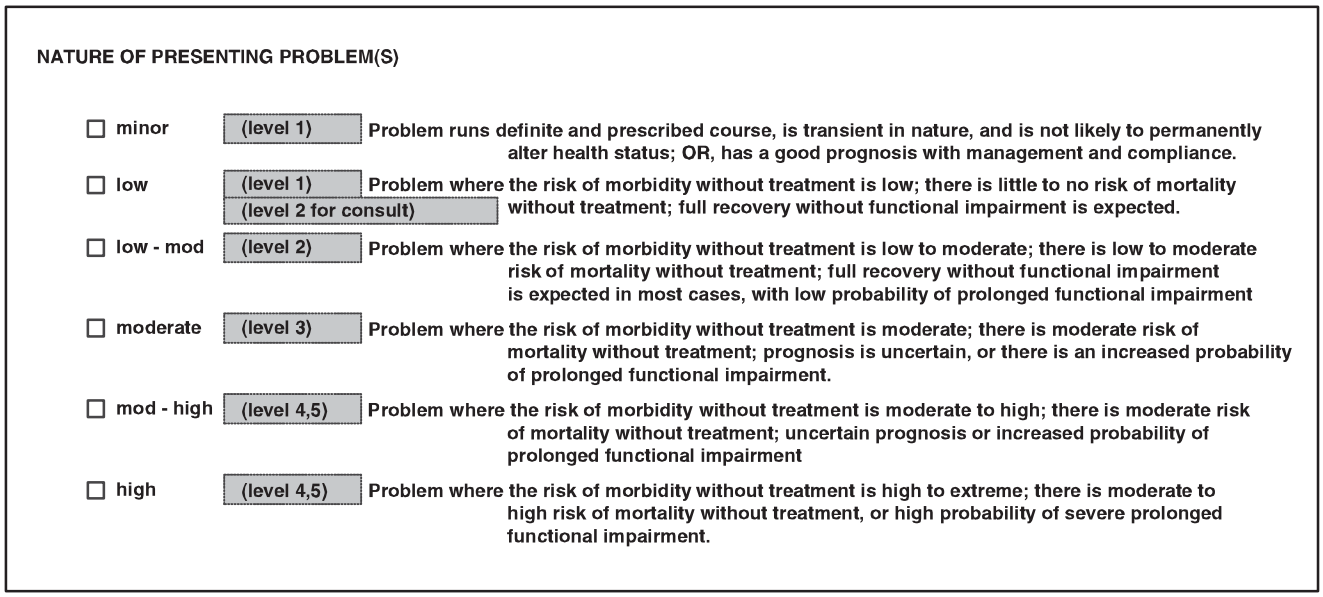

Figure 200.9 Initial Outpatient Visit - Nature of the Presenting Problem(s) (NPP) (44). This section provides CPT descriptions of illness severity associated with various levels of NPP; these are supplemented by associated levels of care presented in the CPT descriptors. Appropriate templates for NPP of established outpatient visits and other types of service are also available (44). Clinical examples, approved by various specialty societies including AAO-HNS, are provided in Appendix C of CPT.

Principle #2: Most surgical procedures include a "surgical package" of additional care services (50). The surgical package also includes expected E/M services related to the procedure for a particular time span. Additionally, the appropriate time span for each procedure is specified by CMS as the "global period," which may be zero days or 10 days for "minor procedures" and is 90 days for "major procedures." Certain other minor procedures (e.g., audiology codes) have an "XXX" designation, which indicates, "the global concept does not apply to the code" (51).

Principle #3: Many procedures include performance of other less complex procedures as "components."

Principle #4: The relative value units (RVUs) assigned to each procedure are determined on the basis of vignettes that take into consideration the procedure itself, the surgical package, and all less complex component procedures. These vignettes are developed by an AMA committee that includes representatives of most major specialty societies, including Otolaryngology—Head and Neck Surgery. They are available in the AMA publication "CPT Reference of Clinical Examples."

Principle #5: CPT principles for correct coding of multiple procedures all seem to reinforce a unifying basic premise: "Every medical service performed should be compensated once, but only once. For example, the physician should not submit a code for E/M services if another service (such as a procedure with a global period, as described below) also includes the value of that same E/M service" (52).

Principle #6: Medicare provides an NCCI that indicates procedures it considers should not be billed (i.e., should not be coded) in combination with other procedures. There are currently more than 600,000 edits in the NCCI (53). Fortunately, most of these are "category 1/category 2" combining (i.e., "bundling") edits that are compliant with CPT's vignettes. However, Medicare also includes "mutually exclusive edits" and defined payment policies that may differ from CPT's assignment of RVUs.

Principle #7: Most private insurers use claims processing software from a common vendor. While these systems also include combining or bundling edits, the number of edits is several magnitudes greater than in NCCI (54); most of the extra edits are necessarily inconsistent with CPT and with NCCI edits, and they are therefore noncompliant. When the explanation of benefits (EOBs) from private insurers deny claims based on these noncompliant edits, the justification is usually conveyed either as one procedure being "incidental to" another or the two procedures being "mutually exclusive." Neither these two terms nor the explanations of what they mean are found in CPT or in NCCI; they are noncompliant with CPT principles and practices.

Unfortunately, even though insurers require medical practices to use the CPT coding system to submit claims, and they pay on the basis of CPT codes, they are not legally required to follow CPT coding compliance principles. Despite this, it remains important for physicians to understand and adhere to proper coding and compliant use of modifiers so that they can identify and challenge noncompliant payment practices they encounter when dealing with payers.

Commonly Used Modifiers for Multiple Procedures

When submitting claims for two or more independent surgical procedures on the same date of service, the modifiers that are most commonly added to all procedure codes other than the principle code are .50, .51, and .59. *The .50 modifier* should be applied whenever the physician performs a *bilateral procedure* at the same session. Examples of correct use of this modifier are

- 69436.50 to report bilateral tympanostomy with insertion of tubes (under general anesthesia)
- 31255.50 to report bilateral endoscopic total ethmoidectomy (surgery on anterior and posterior ethmoid cells)
- 30901.50 to report bilateral control of anterior nasal hemorrhage (simple)

These example codes show procedures that are also frequently performed unilaterally, so the RVU values assigned to them incorporate the value of a single procedure. For

services that are most often performed as bilateral procedures or whose CPT descriptions specify that the procedure is designated as bilateral, it is not necessary or appropriate to add the .50 modifier. Examples of intrinsically bilateral codes include

- 42826: Tonsillectomy, age 12 or over (*this is an example of an intrinsically bilateral procedure*)
- 30801: Ablation, soft tissue of inferior turbinates, *unilateral or bilateral*, any method

The .51 modifier is appropriate when two procedures are performed, and one is not a component of the other. This modifier signals to the payer's software that the procedures are independent, and they should both be paid. The highest valued code should always be listed first, without the .51 modifier, because (as noted below) this procedure will be paid at full value while the others are each paid at 50% of their value. A common example of correct use of this modifier is

- 31254 (endoscopic anterior ethmoidectomy), 31256.51 (endoscopic maxillary antrostomy)

CPT describes that the .59 modifier is to be used to indicate a "distinct procedural service." This meaning is further clarified by stating that it "is used to identify procedures/services, other than E/M services, that are not normally reported together, but are appropriate under the circumstances. Documentation must support a different session, different procedure or surgery, different site or organ system, separate incision/excision, separate lesion, or separate injury" (55). CPT further cautions, "When another already established modifier is appropriate, it should be used rather than modifier 59" (55). An example of correct use of this modifier is

- 31255 (endoscopic total ethmoidectomy), 31254.59 (endoscopic anterior ethmoidectomy)
  - When performed on the same nasal passage, 31254 is a component of 31255 and should not be billed separately. However, if the procedures are performed on opposite sides of the nose, the .59 modifier is required to indicate that the procedures were not performed in the same location.
  - The .51 modifier could not be appropriately used, because software programs would assume the coding was for both procedures on the same side and would disallow the 31254 completely.

The .59 modifier is effective in indicating that payment is appropriate for otherwise non-billable code combinations. However, it must only be used judiciously and correctly, as excessive use will likely trigger an audit and significant financial penalties if improper utilization is found.

From the perspective of insurer payments, unfortunately Medicare long ago made a decision that it would reduce payments by 50% for all secondary procedures (those submitted with a .50, .51, or .59 modifier). This decision came in 1992 with the introduction of the RBRVS system and a unilateral determination that the absence of distinct pre- and postoperative care for the secondary procedures justified the reduction. Almost all surgeons would dispute the validity of such a severe reduction, and its magnitude is even self-contradicted by Medicare's use of only a 20% reduction when a surgeon delegates pre- and postoperative care to another clinician (indicated by use of modifier .54). However, this is a long-standing policy for Medicare, and it is duplicated by almost all private insurers (although some implement even greater reductions for third and fourth procedures).

Commonly Used Modifiers for E/M Services Related to Procedures

All diagnostic and surgical procedures that have an associated global period are subject to the guidelines of the surgical package definition, and the RVUs designated for these services *include* all E/M services provided under two particular circumstances:

- "Subsequent to the decision for surgery, one related Evaluation and Management (E/M) encounter on the date immediately prior to or on the date of the procedure (including history and physical)."
- "Typical postoperative follow-up care" (56)

These guidelines advise that *under normal circumstances an E/M code should not be submitted when a procedure is performed on the same day* (because the value for this service is already included in the value assigned to the procedure). However, there are several defined circumstances in which the E/M service is more extensive than normally anticipated. When these conditions arise, physicians are advised to submit a code for the E/M service with an appropriate modifier. The three modifiers that may apply are .24, .25, and .57.

Compliant use of the .25 modifier, "significant, separately identifiable evaluation and management service by the same physician on the same day of the procedure or other service": Although E/M services on the day of a procedure are included in the "surgical package," certain well-defined circumstances warrant submission of an E/M code with a .25 or .57 modifier attached. The .25 modifier is applied only for minor procedures, that is, procedures with a zero-day or 10-day global period. The two situations that should justify this coding are

- If "the patient's condition required a significant, separately identifiable E/M service above and beyond the other service provided or beyond the usual preoperative and postoperative care associated with the procedure that was performed" (57). This situation is most commonly appropriate when the procedure is performed for one diagnosis (e.g., nasal endoscopy performed for evaluation of chronic sinusitis), and the E/M service is performed for a separate problem (e.g., acute otitis

externa). With two *unrelated* diagnosis codes, a payer's claims processing software should readily identify that the E/M service was for a significant and separately identifiable condition.

- If the E/M care resulted in the decision to perform a minor or diagnostic procedure, because CPT coding guidelines specify that the surgical package includes (only) E/M care that is performed "subsequent to the decision for surgery"

However, the case of E/M as the basis of the decision for a minor procedure still requires a significant and separately identifiable E/M service, not simply problem-focused care. This interpretation is clarified in the Medicare RBRVS Physician's Guide section describing minor surgeries and endoscopies: "Payment for a visit would be allowed in addition to payment for suturing a scalp wound if, in addition, a full neurologic exam is made for a patient with head trauma. If the physician only identified the need for sutures and confirmed allergy and immunization status, billing for a visit would not be appropriate" (58).

An excellent example of *appropriate* use of the .25 modifier with decision for surgery would be an initial visit for a patient who is a smoker, has three months of persistent hoarseness, and has a hyperactive gag reflex that precludes an adequate mirror examination of the larynx. Since this is an initial visit, it is logical and obvious that the E/M service was the basis for making a decision to perform a medically indicated fiberoptic laryngoscopy (CPT code 31575). Therefore, the appropriate E/M code should be submitted with a .25 modifier (assuming the physician performs and documents an appropriately high level of E/M service that is warranted for this patient). Unfortunately, there is a significant billing/payment challenge under the same circumstances if the patient is an established patient in the practice and presents with a new problem. When the same (or a related) diagnosis code is submitted for both the procedure and the E/M service, the payer's software has no means of confirming that the E/M service was truly the basis for the decision to perform the procedure. "The result is frequently denial or delay of claims processing, necessitating appeals for payment and causing significant administrative burden for the physician's staff" (59).

Compliant use of the .57 modifier, "decision for surgery": The CPT codebook specifies only that this modifier is used with an E/M service that results in the initial decision to perform surgery. However, Medicare provides clarification that specifically differentiates correct use of the .57 modifier from modifier 25, by stating, "use of modifier .57 is limited to operations with 90-day global periods" (60). A hypothetical example for use of this modifier would be evaluation in the emergency department of an adult patient found to have a large parapharyngeal space abscess. The E/M evaluation would be billed (e.g., 99284.57) as the basis for the decision to take the patient to the operating room and perform an open draining of the abscess (CPT code 21501, which has a 90-day global period).

Compliant use of the .24 modifier, "unrelated evaluation and management service by the same physician during a postoperative period." Most diagnostic procedures, such as fiberoptic laryngoscopy and fiberoptic nasal endoscopy, are assigned a zero-day global period. Therapeutic surgical procedures may have global periods of 0, 10, or 90 days. Normally, no E/M codes should be submitted during the designated postoperative time frame. There are, however, two circumstances under which an E/M code should be submitted with an attached .24 modifier:

- Provision of an E/M service for a problem unrelated to the original procedure. For example, if a patient who has undergone a superficial parotidectomy develops acute ethmoid sinusitis during the 90-day global period, the evaluation and management of this episode should be coded (e.g., CPT code 99213.24 with a diagnosis code of 461.2).
- Treatment of a postoperative complication. CPT's surgical package description of "typical" follow-up care encompasses the E/M services normally provided during the assigned global periods (0, 10, or 90 days). CPT further specifies. "Complications, exacerbations, recurrence, or the presence of other diseases or injuries requiring additional services should be separately reported" (61). Therefore, if the patient who is postoperative from a superficial parotidectomy develops a fistula, the E/M care of this complication should be coded and submitted (e.g., 99213.24 with a diagnosis code of 527.4 [salivary gland fistula]).

The Medicare Conundrum for Billing Postoperative Complications

Although in most instances Medicare's national policy for use of modifiers is compliant with CPT conventions, it has unilaterally adopted a number of "payment rules and policies" that contradict certain principles of the CPT coding system. One such policy concerns reimbursement for complications that occur during the global period of an operation. Instead of recognizing that the RBRVS values for surgical procedures do not include any RVUs for potential care of postoperative complications, Medicare will not provide payment for any medical or surgical care that does not require a trip to the operating room. Its policy states, "Medicare will include these services (*for complications*) in the approved amount for the global surgery with no separate payment made" (62). Medicare therefore instructs that physicians should not submit any claims for E/M services provided for care of complications during the postoperative global period.

CODING AND BILLING RISKS AND CHALLENGES IN OTOLARYNGOLOGY—HEAD AND NECK SURGERY

Precise descriptive documentation of procedures and E/M services is the foundation for accurate coding. When applied to the billing process, documentation and coding are subject to review by Medicare and insurance carriers, which can lead to two potential issues for medical practices.

The first issue is that practices must be alert to the potential for insurers' noncompliant payment practices through improper "bundling" of payments and/or denial of services. For example, insurers have at times programmed their claims processing software to improperly deny payment for performance of a nasal septal reconstruction (CPT code 30520) by "bundling" it into endoscopic sinus surgery procedures (e.g., CPT code 31254), using the improper and nonspecific rationale that the septum operation is "incidental to" the performance of the sinus surgery. This noncompliant payment practice was another of the critical issues in the national class action lawsuits filed by physician organizations against health insurers in the first decade of the 21st century (63). Practices must rise to the challenge of meticulous scrutiny of each line item of the EOBs they receive from payers, with follow-up inquiries and appeals to attempt to receive correct payment. This important concern is covered in the chapter on billing and accounts receivable.

The second issue is that practices must be alert to compliance risks and potentially severe financial penalties in the event of audits of their coding and documentation practices by Medicare and/or private insurers. Although Medicare in particular does perform "random reviews," the use of "targeted audits" is more prevalent, from Medicare-related organizations and private insurers alike. Targeted reviews are initiated when an automated (by computer) analysis of a physician's coding and billing patterns reveals statistically significant disparities in frequency and/or intensity of services when compared with the patterns of fellow practitioners. This finding then triggers a request for medical records, which are evaluated by trained reviewers for appropriateness of care and coding.

In the event of an audit by a MAC, other government agency (64), or private insurer, payment will be denied if the physician's medical documentation is inadequate to support performance of the services claimed, if the coding is inaccurate (i.e., inadequate ***specificity***), or if the documentation fails to support ***medical necessity*** for performing the care. If the audit reveals only occasional problems, the medical practice may be provided educational materials and re-reviewed within a reasonable time frame. On the other hand, consequences escalate dramatically if a review reveals a high frequency of improper coding practices:

- At a minimum, the practice will be required to refund the improper payments identified in the audits. (It is noteworthy that under the requirements of the recently passed Affordable Health Care for America Act, practices must promptly self-report any overpayments they identify, or they face additional financial penalties for nonreporting.)
- If medical record documentation consistently fails to support the specificity or medical necessity of claims submitted, the MAC or insurer may extrapolate the discovered errors to include all claims for those identified services filed over a period of multiple years. Extrapolation can result in economically devastating repayments.
- Practices may be placed under a "corporate integrity agreement" (CIA), requiring strict independent oversight of a formal compliance plan and prepayment review of all claims.
- Under more egregious circumstances, a MAC auditor (or an auditor from the OIG or other government agencies) may conclude that such unsupported bills were "false claims," resulting in additional fines of up to $11,000 per claim. This determination may even lead to criminal prosecution.
- Practices may be prohibited from participation in the Medicare or Medicaid programs.

Recognized Risk Areas

While some recognized risk areas for disparities in coding and billing practices relate to lack of specificity or misunderstanding of component procedures, the most prevalent risk category is failure of the documentation to support ***medical necessity***. This vulnerability includes risks related to levels of E/M care, decisions for surgery, timing of surgery, and extent of surgery. As noted above in the definition of medical necessity agreed upon in the national class action lawsuit settlements, medical necessity includes care that is "in accordance with generally accepted standards of medical practice" (65), and those accepted standards include "standards that are based on credible scientific evidence published in peer-reviewed medical literature generally recognized by the *relevant* medical community, Physician Specialty Society recommendations…" (66). In the specialty of Otolaryngology—Head and Neck Surgery, the Quality Improvement Committee and appropriate specialty committees of the AAO-HNS have adhered to the practices of "EBM" in evaluating applicable peer-reviewed medical literature to compile its Clinical Indicators Compendium, Policy Statements, and Clinical Practice Guidelines and Clinical Consensus Statements (cited previously as resources for compliance). As noted below, the tenets of EBM advocate using best evidence and guidelines as a starting point for care; that is, they should be considered a platform and not a box. However, *it is incumbent upon physicians to* ***document*** *the basis for care decisions that significantly vary from these standards*, particularly if they are to withstand reviews for compliance and quality of care.

As one perplexed physician reviewer observed in evaluating coding for the performance of endoscopic sinus surgeries, "the decisions for timing and extent of surgery relate to physician preferences rather than to patients' medical indications."

Fundamentals of Evidence Based Medicine (EBM)

Dr. David Sackett, commonly recognized as the "father of evidence-based medicine," describes the principles and practice of EBM as the integration of best clinical evidence with individual clinical expertise and patient's individual values and expectations: "EBM is the conscientious, explicit and judicious use of current best evidence in making decisions about the care of individual patients. The practice of EBM means integrating individual clinical expertise with the best available external clinical evidence from systematic research… Good doctors use both individual clinical expertise and the best available external evidence, and neither alone is enough. Without clinical expertise, practice risks becoming tyrannized by external evidence, for even excellent external evidence may be inapplicable to or inappropriate for an individual patient. Without current best external evidence, practice risks becoming rapidly out of date, to the detriment of patients" (67).

Specific Coding and Billing Risks

Following is an overview of some of the most significant risk areas in Otolaryngology—Head and Neck Surgery, selected by frequency and intensity of service, including a brief summary of critical compliance concerns.

Evaluation and Management Coding (E/M)

1. **Indicators for potential risk**: Frequent use of high-level E/M codes (i.e., level 4 and level 5), particularly in association with diagnosis codes not usually associated with relatively high severity illness (i.e., moderate to high NPP)
   a. See Appendix C of CPT for Clinical Examples of patients whose severity of illness (NPP) is deemed sufficient to warrant various levels of care.
2. **Documentation dangers**: E/M documentation frequently fails to comply with principles presented in CPT and the Documentation Guidelines. This particularly includes failure to document qualitative features of E/M, the three levels of risk, and an assessment of the NPPs.
   a. Risk levels may be significantly increased in many EHRs that use noncompliant screen designs and noncompliant data entry shortcuts (resulting in "cloned" documentation).
   b. Reports of Medicare/OIG audits of physicians using such noncompliant EHRs have documented repayment penalties in excess of $175,000 per physician (68). Noncompliant E/M coding in EHRs is near the top of the OIG's list of items to audit in its 2011 - 2013 work plans.

Ear Procedures

1. **Removal of ventilation tube(s) in the operating room (CPT code 69424)** (performed for prolonged retention).
   a. **Indicators for potential risk**: Codes submitted for performing a tympanic membrane repair (CPT code 69610), myringoplasty [69620], or tympanoplasty without mastoidectomy [69631] instead of, or in addition to, code 69424 (particularly if performed routinely)
   b. **Compliance risk**: Standard practice followed by most physicians is removal of the retained tube allowing spontaneous closure without the ***medical necessity*** of a repair procedure; there is no *evidence* for a significant failure rate of this less complex treatment.
      i. If there are conditions in a specific case warranting such a repair (e.g., a widened perforation or a monomeric membrane around the retained tube), these should be well-documented in the medical record and in the "indications" section of the operative report; additional diagnosis code(s) might also be indicated.
   c. Note: If tube removal is performed in office setting, no procedure code is applicable; the procedure is a component of the E/M service.

Nose and Sinus Procedures

Review of the coding and billing practices related to most of the procedures in this section reveals significant physician disparities in frequency of performing the procedures, timing of performing the procedures, and/or extent of procedures performed. Detailed review of documentation frequently reveals additional disparities among physicians in clinical indications for performing the procedures. These variations occur despite the existence of evidence-based standards for care and the absence of clinical evidence of significant differences in outcomes with more extensive techniques.

1. **Diagnostic nasal endoscopy** (CPT code 31231)
   a. **Indicators for potential risk**: Codes submitted with high frequency, especially when associated with diagnostic codes not commonly associated with ***medical necessity*** for performing this procedure and particularly when employed during an initial evaluation of a new medical problem
   b. **Compliance risk**: The appropriate ear, nose, and throat physical examination (under both 1995

and 1997 Documentation Guidelines protocols) includes an intranasal examination using anterior rhinoscopy, with or without utilization of a topical decongestant spray. Routine use of a nasal endoscope to perform all or part of this standard intranasal examination, instead of or in addition to use of anterior rhinoscopy, is considered to be "primarily for the convenience of the physician," and it therefore fails to meet the criteria for "***medical necessity***." Figure 200.2's documentation form for nasal endoscopy includes a number of clinical indications that support the medical necessity of performing this procedure to supplement anterior rhinoscopy.

2. **Nasopharyngoscopy with (fiberoptic) endoscope** (CPT code 92511)
   a. **Indicators for potential risk**: Codes submitted with high frequency, especially when associated with diagnostic codes not commonly associated with ***medical necessity*** for performing this procedure
   b. **Compliance risk**: The appropriate ear, nose, and throat physical examination (under both 1995 and 1997 Documentation Guidelines protocols) includes a mirror examination of the nasopharynx. Routine use of a fiberoptic endoscope to perform this standard examination instead of or in addition to use of a mirror, while clinically acceptable, is considered to be "primarily for the convenience of the physician," and it therefore fails to meet the criteria for "***medical necessity***." Documentation of medical necessity should include two components: (a) the medical indication for examining the nasopharynx and (b) a reason why mirror examination provides inadequate visualization.
3. **Turbinate surgery**: Mucosal cauterization (CPT codes 30801 and 30802), partial or complete resection inferior turbinate (CPT code 30130), submucous resection inferior turbinate (CPT code 30140), and therapeutic fracture of inferior turbinate (CPT code 30930)
   a. **Indicators for potential risk**: Codes submitted with high frequency, particularly as a *routine* component of most sinus operations and/or nasal septal reconstructive surgery
   b. **Compliance risk**: The AAO-HNS "Clinical Indicators Compendium" emphasizes that one of the *required* indications for performing surgery of the inferior turbinate is "chronic nasal obstruction, *management inadequate*" (69). Standard management for unilateral compensatory turbinate hypertrophy associated with a deviated nasal septum is correction of the septal deformity, with physiologic return to normal mucosal thickness and airway patency over a relatively short period of several weeks. Similarly, standard management for reactive turbinate hypertrophy associated with chronic unilateral or bilateral sinusitis is medical or surgical correction of the sinus pathology, with physiologic return to normal mucosal thickness and airway patency over a relatively short period of several weeks. These guidelines reserve turbinate intervention solely for those unusual cases that demonstrate continued turbinate pathology with airway obstruction after this primary surgical management. Therefore, the routine use of turbinate surgery, prior to evaluating the outcome of corrective surgery, appears to be "primarily for the convenience of the physician," and it therefore fails to meet the criteria for ***medical necessity***.
4. **Endoscopic sinus surgery**: Anterior ethmoidectomy (CPT code 31254), total ethmoidectomy (CPT code 31255), maxillary sinusotomy (CPT codes 31256 and 31257), frontal sinus exploration (CPT code 31276), and sphenoidotomy (CPT codes 31287 and 31288)
   a. **Indicators for potential risk**: Two high-risk issues stand out in reviewing coding and billing patterns for endoscopic sinus surgery. The first is frequent or consistent performance of surgery in close proximity to the initial evaluation for nasal and sinus symptoms, which suggests significant variance from ***medical necessity*** guidelines. The second risk factor is high frequency of multiple procedures during each surgical episode; that is, many or most surgeries including total ethmoidectomy, frontal sinus surgery, and/or sphenoid sinus surgery. This finding suggests the possibility of significant variance from both *specificity* and *medical necessity* guidelines.
   b. **Compliance risk**: The AAO-HNS "Clinical Indicators Compendium" provides comprehensive guidelines on appropriate indications for performing endoscopic surgery as well as specifications that affect timing and extent of surgery. These include "failure of medical management for chronic sinus pathology … *(including)* optimal medical therapy prior to obtaining sinus CT scan, prior to nasal endoscopy, and prior to surgery … *(this therapy includes)* antibiotic therapy consisting of four to six consecutive weeks of appropriate antibiotic drugs" (70). The timing required for adequate medical therapy raises significant concerns when claims consistently reveal performance of surgery in less than 6 weeks after initial consultation. Another of these guidelines relates medical necessity for each component of surgery to specificity of diagnostic findings: "Surgical procedure and findings must be compatible with clinical status, CT findings, and nasal endoscopic findings *(all determined after optimal medical therapy)*. That is, only patients with significant persistent sinus symptoms and pathology should undergo surgery" (71). High frequency of multiple extensive surgeries, particularly after optimal medical evaluation and therapy, is also inconsistent with the practices of many physicians who experience excellent outcomes with endoscopic surgery that in the majority of cases is confined to the anterior ethmoid sinus and the maxillary ostium.

c. Sinus care and documentation should reflect the standards presented in the Clinical Indicators Compendium. In the event of variance from these standards, documentation should clearly support the medical indications for discrepancies.

5. **Debridement** (CPT code 31237)
   a. **Indicators for potential risk**: Codes submitted for a significant majority of cases of endoscopic sinus surgery, particularly with multiple and frequent debridements. Claims reviews commonly reveal that physicians who submit for multiple debridements do so in essentially every case. Particular concern relates to both ***medical necessity*** for performing the procedures and whether the procedures performed meet the ***specificity*** required to qualify as a true debridement (rather than just cleaning debris).
   b. **Compliance risks**
      i. In the postoperative management of primary and noncomplex endoscopic sinus surgery patients, there is no *evidence* of more favorable outcomes in patients undergoing multiple debridement procedures. In its Policy Statement on Debridement of the Sinus Cavity after FESS, while the AAO-HNS affirms, "The frequency with which the above mentioned procedure should be performed is a clinical judgment best made by the surgeon," it also advises that this frequency should be "*determined on a case by case basis*" (72). However, for surgeons whose use of debridement following noncomplicated procedures is *routine* rather than individually determined, it appears to be "primarily for the convenience of the physician" and therefore fails to meet the criteria for ***medical necessity***.
      ii. Of greater concern is a potential ***specificity*** issue related to submission of claims for nasal cleaning treatments whose intensity of service fails to qualify as a true debridement. The AAO-HNS Policy Statement on debridement also specifies that debridement "involves transnasal insertion of the endoscope for visualization and parallel insertion of various instruments for the purpose of removal of postsurgical crusting, devitalized mucosa or other contaminated tissue. *It is performed under local or general anesthesia* in an office suitably equipped or operating room, depending on the clinical circumstances of the case" (72). However, documentation of debridement procedures frequently reports only use of suction and forceps to remove loose crusts, rather than more demanding procedures requiring injected local anesthesia or general anesthesia. Such documentation fails to support the ***specificity*** required to code for a true debridement procedure.

Oral Cavity

1. **Coding for uvulopalatopharyngoplasty (UPPP) and tonsillectomy** (CPT codes 42145 and 42826):
   a. **Indicators for potential risk**: Most surgeons express the opinion that the combination of these two procedures involves greater skill, effort, and time than performing a UPPP alone. However, Medicare's NCCI edits designate tonsillectomy to be a component service of the UPPP procedure. Therefore, submitting claims for performing both services during the same operation is an example of "unbundling." In other words, the value of a tonsillectomy is included in the RVUs assigned to the more complex UPPP procedure, so it should not also be coded and billed separately.

Larynx

1. **Flexible fiberoptic laryngoscopy** (CPT code 31575):
   a. **Indicators for potential risk**: Codes submitted with high frequency, especially when associated with diagnostic codes not commonly associated with ***medical necessity*** for performing this procedure
   b. **Compliance risk**: The appropriate ear, nose, and throat physical examination (under both 1995 and 1997 Documentation Guidelines protocols) includes a mirror examination of the larynx. Routine use of a fiberoptic endoscope to perform this standard examination instead of, or in addition to, use of a mirror, while clinically acceptable, is considered to be "primarily for the convenience of the physician," and it therefore fails to meet the criteria for "***medical necessity***." Documentation of medical necessity should include two components: (a) the medical indication for examining the larynx and (b) a reason that mirror examination provides inadequate visualization. The documentation form for fiberoptic laryngoscopy shown in Figure 200.2 includes a number of clinical indications that support the medical necessity of performing this procedure.

SUMMARY

High-quality documentation accurately reflects the procedures and cognitive services physicians provide for their patients. In addition, the introduction of effective documentation templates that integrate compliance principles and enable efficient data entry can facilitate accurate coding and actually promote quality patient care. Even when working in practices that include certified professional coders, physicians need to understand and practice the basic concepts of compliant documentation and coding. Not only does their knowledge assist coders by providing the specificity they require for accurate identification of services, but it is also addresses the critical area of medical necessity, which only physicians can provide. For the

practice of Otolaryngology—Head and Neck Surgery, the "generally accepted standards of medical practice" that are the foundation of medical necessity include the evidence-based recommendations found in the AAO-HNS's Clinical Indicators, Policy Statements, and Practice Guidelines.

HIGHLIGHTS

- The E/M coding system is actually derived from the recognized medical student text "Bates' Guide to Physical Examination and History Taking."
  - The E/M system is therefore a codification of the medical diagnostic process that all physicians learn in their training as being the most effective method for providing high-quality patient care.
  - Therefore, compliantly designed medical record tools can actually help physicians provide optimal care within a time frame that meets the limitations of the current health care environment.
- Physicians require a toolkit of usable, efficient, and compliant data entry options for efficient and compliant documentation, including
  - Proper application of graphic and narrative interface designs
  - Proper application of templates, with limited and cautious use of macros
  - Optimal use of appropriate data entry personnel, including staff and/or patients
  - Optimal use of appropriate data entry modalities for dictation, legible handwriting, and/or keyboard and mouse (with electronic health records)
- Coding principles rely on reporting the most appropriate procedure codes using CPT designations and the most appropriate diagnosis codes using ICD-9 designations:
  - Codification has multiple uses, including reporting for CER, population studies for public health, and (in the United States) submission of claims for payment.
- The critical factors in achieving compliant coding and documentation are specificity and medical necessity.
  - Specificity is required for selection of correct procedure and diagnosis codes.
  - Medical necessity is a central factor in appropriateness of claims, including consideration of standards of care and application of evidence-based medicine.
- The three central concepts to compliant coding and billing are:
  - "Medical necessity of a service is the overarching criterion for payment in addition to the individual requirements of a CPT code."
  - "If medical care is not documented in the medical record, it is treated as if it had not been performed."
  - "Automation is not documentation."
- Physicians' requirements for effective medical record documentation and coding tools include usability, efficiency, compliance, data integrity, promoting quality patient care, and appropriate productivity.
  - Appropriate template designs for procedures and for evaluation and management services (E/M) incorporate specificity and medical necessity to fulfill these goals.
- Physicians at teaching hospitals can and should incorporate the concepts of Medicare's compliance requirements (IL-372 and section 15016 of the Carriers Manual) to integrate personal problem-focused care and documentation plus teaching responsibilities with the comprehensive care and documentation provided by their resident physicians. This requires compliant E/M documentation tools for the residents and compliant "physician presence" documentation tools for the teaching physicians.
- To ensure proper billing and payment, physicians need to understand the basic concepts related to the RBRVS and appropriate use of modifiers.
- Physicians should be aware of noncompliant payment practices employed by Medicare and private insurers to improperly "bundle" services and deny appropriate payments.
- Physicians should be aware of possible compliance risks and potentially severe financial penalties in the event of audits of their coding and documentation practices by Medicare and/or private insurers:
  - A number of recognized risk areas are reviewed for both E/M services and specific procedures.
  - Physicians should be aware of and familiar with standards of care compiled by the AAO-HNS in its "Clinical Indicators," "Policy Statements," and "Clinical Practice Guidelines and Clinical Consensus Statements."

201 Clinic Management

Dana E. Habers *Scott P. Stringer*

ABSTRACT

This chapter works in concert with others in this book to provide residents, medical students, and physicians with a high-level overview of the core skills required to successfully manage a clinical practice. It is meant to build a practical awareness of ambulatory (outpatient) clinic operations, not as an exhaustive manual. The core elements of establishing a practice, promoting access for patients to your services, retaining patients and referral sources, and sustaining financial viability are discussed. The core elements of a clinical practice include

- Human Resources
- Access Management
- Clinic Efficiency
- Managed Care Contracting and Financial Management
- Critical Communication and Protecting Patient Privacy
- Information Technology
- Marketing

Beyond the operating and exam room, there are fundamental skills critical to a physician's success in the medical business. Too many medical students and residents graduate with high honors and a list of academic achievements, but fail in their careers because of a lack of basic business savvy. A full business education is simply too vast to include in the educational journey of a medical school and residency, and this chapter outlines the core skills required to successfully manage a clinical practice and a practical understanding of ambulatory (outpatient) operations. Throughout the text, *Key Resource* inserts are included that lead to more extensive sources of information on each subject.

HUMAN RESOURCES

Above all else, personnel and the human element of any clinical practice will drive its success. Management is one area where the art to medical science comes into play; it requires a significant time investment and is the area most likely to provide a return on investment than any other aspect of clinic management. People make the business. From the provider and their staff to the patients and their families, having the right people on the team will make all the difference.

Whether a physician is in private practice or joins the faculty of a large academic medical center, their role in clinic is inherently that of a leader. The physician sets the tone for a practice, and support staff will revere and respect a physician who is a good leader. What good news for the ego, but the responsibility that comes with this role cannot be underestimated. Leadership is refined with experience and does not come naturally to every medical school graduate. It is worth the time and energy for physicians to hone their leadership skills and work towards greatness in this regard. Top leaders are "differentiated from other levels of leaders in that they have a wonderful blend of personal humility combined with extraordinary professional will. Understand that they are very ambitious; but their ambition, first and foremost, is for the company's success. They realize that the most important step they must make to become a Level 5 leader is to subjugate their ego to the company's performance. When asked for interviews, these leaders will agree only if it's about the company and not about them" (1).

Beyond the physician, the people supporting their provision of care carry tone and culture throughout the practice. Relationships between the physician and patient are pivotal, but the amount of time patients spend interacting with the clinic staff far outweighs time spent with their physician. A positive patient care experience hinges on whether each team member they interact with consistently demonstrates helpfulness and kindness and promotes an environment of safety, security, and confidentiality. Hiring staff who subscribe to common philosophies on customer

service and priorities in the workplace forms the foundational stability for a thriving, oftentimes unpredictably busy clinical practice.

In addition to hiring the right people for the right roles, it is important to rightsize the number of employees. There are several organizations in the market that offer benchmarking data for staffing levels. It is important to gauge, but difficult to compare unequivocally to other practices, as support needs vary widely from practice to practice and will depend on several factors.

Key Resource: Health Care Management Networking

Several health care management organizations exist for benchmarking and idea sharing: to name a few, the Medical Group Managers Association, Healthcare Financial Management Association, Healthcare Information and Management Systems Society, American College of Healthcare Executives, and many more that dive deeper into specialties or delineate between academic medicine and private practices.

Patient volumes, socioeconomic characteristics of the patient population, mix of services provided, and even the physician's personal style of practice all factor into determining the right number of support staff per physician. Key operational roles include registered nurses (RNs); licensed practical nurses (LPNs); medical assistants (MAs); and nonmedical administrative support including management, schedulers, patient accounting, housekeeping, information technology, and medical receptionists.

Retention of excellent employees saves a practice both time and money and improves the quality of care. National studies have estimated the average cost of replacing an RN to be anywhere from about $22,000 to over $64,000 (2). Turnover costs are estimated to range between 0.75 and 2.0 times the salary of the departing individual (3), while nurse turnover costs have been estimated at 1.3 times the salary of a departing nurse (4). Patient care can suffer when the nursing and administrative staff members are inexperienced or unfamiliar with the clinic operations.

Beyond just being a great leader and setting a productive cultural tone, there are tactical strategies to retain good people. Making the financial investment in your staff is the most obvious. Paying market-competitive salaries that keep pace with inflation and offering a competitive benefits package to supplement take-home pay are strategies. People are also motivated by nonmonetary rewards and recognition that can be as simple as a note of appreciation when they've done a good job or getting recognition for making a positive impression on a patient. Retention is not a mystery—consider what drives each individual on your team and ensure that his or her intrinsic needs to be a happy and productive employee are met. Support the sharing of ideas, get to know staff, and listen to their concerns. Provide opportunities for their personal and professional growth. These are valuable investments in the core of the clinical practice, the people.

ACCESS MANAGEMENT

Access to health care has sparked ongoing debate and political division in the United States for years. Physicians are inherently committed to treating patients who come to them in need of care. However, health care professionals are not immune to economic realities. In the current system, the cost of health care often exceeds individual affordability. While many Americans have insurance coverage, there are a vast number of individuals and families who do not. There are also people with high deductible insurance plans who, while covered by an insurance plan, will struggle with affordability. Health care providers must balance both missions: to provide care to those in need, while remaining viable as a business and able to sustain continued services over the course of time. Increasingly, ethical pressure builds on the physician to walk this fine line.

One method used to promote sustainability is to divide a portion of patient appointment slots between various payer classes. This mechanism builds in both the accommodation of patients with a variety of payment sources as well as the funding from enough insured patients to sustain the practice.

Logistical access points are another component of access to health care. Requests for physician services come from a variety of constituents: referring primary care doctors, referring specialists, their office staff, and patients themselves. To accommodate all requests, it is advisable to develop policies and consistent protocols around both who is authorized to refer a patient to the clinic and what process they must follow to do so. For example, if a referring physician calls to request an appointment for one of his or her patients, copies of applicable clinical information from the patient's chart will need to be sent prior to the appointment. Labs or other ancillary test results from outside sources will avoid ordering duplicate studies or tests and achieve a continuum of care for the patient. Such policies must be built in advance and adhered to consistently in order to ensure equity in access. Another consideration in access points is how requests are received—whether by inbound phone, fax, e-mail, or other mechanisms, a quick turnaround and bidirectional communication with the requester is important to promote access and survive in a competitive market. Acquiring a reputation of being difficult to access or slow to respond to appointment requests will quickly drive referring physicians to send their patients elsewhere.

Scheduling template design is also critical. It impacts not only revenue but also clinic throughput, efficiency, staff morale, and patient satisfaction. Length of appointment will naturally vary by provider, but a good rule of thumb

for a new physician starting to build the practice is to allot 15-minute increments for every standard patient visit. The template can be adjusted accordingly to properly account for a typical new or established patient visit with each provider.

There are several examples of template design techniques that can be used to promote access, the most common include

- Stream scheduling: Patients are each given a unique appointment time and arrive in a steady stream throughout clinic. Setting realistic appointment times is critical for smooth patient flow. This is the most common model.
- Open access: No appointment is required. Patients are seen during specified hours on a first-come, first-serve basis. This technique works well for brief visit types and when clinic staffing levels are flexible to accommodate variations in demand.
- Double booking: Two or more patients are given the same appointment time. This works best for patients whose needs can be met simultaneously, for example, patient A requires lab work and will have a wait time while results are processed, during which the physician can see patient B for suture removal. Double booking is also used where patient populations have a high rate of no shows or last-minute cancellations, in order to ensure a full schedule despite last-minute decline in patient demand.
- Clustering: Patients with similar problems or who require an assembly line procedure are seen consecutively. This is useful if the patient care involves a particular piece of equipment and efficiencies are gained by seeing patients back to back.
- Wave or modified wave scheduling: Two or three patients who have complex or time-consuming problems are scheduled at the beginning of each hour, followed by single appointments every 10 to 20 minutes the rest of the hour devoted to patients with minor problems or for same day walk-ins. In wave or modified wave, the appropriate triage of patient needs when scheduling the appointments is critical to success.

Once an appointment is scheduled, the process to obtain approval for any procedures should begin immediately. The difficulty for physicians in this system is that each insurance company typically develops a unique set of rules around which procedures require an authorization, the process physicians must follow to obtain pre-approval, and even the level of detail or data sets required to obtaining an authorization. The best approach is to have dedicated office personnel for this function who can become familiar with each of the rule sets, keep abreast as they change, and allow as much time as possible to follow their protocols before a service is rendered.

The patients' arrival to the clinic presents a prime opportunity to validate their demographic and insurance information. This information must be accurately captured to process medical claims or advance their account through the collections cycles for payments due after the date of service. Many insurance companies provide eligibility verification tools on their Web sites, or there are clearinghouse vendors whose technology will automatically validate discreet data fields against various insurance company databases to guide correction of inaccuracies.

CLINIC EFFICIENCY

Physicians in training are often criticized for the time it takes to do many of the things they have been taught to do well. For example, documentation that is thorough and detailed takes time, as does visiting with a patient during a routine evaluation and management visit. However, in order to stay afloat, a clinical practice will survive off volume. As long as the reimbursement environment is based on a fee-for-service infrastructure, the more services a physician can provide in a day, the more financially viable the physician's practice will be. The challenge for physicians is to find balance and work towards efficiency, trimming any wasted time from the day. Clinic layout and flow is one way to save steps for physicians, nurses, and other support staff. It is important to have the right number of support staff, but each one must have the ability to do his or her job efficiently and without, or at least with minimal, waste.

Bottlenecks can arise in the physical layout of the clinic space, the stocking and flow of medical supplies and equipment, or even in the logistical characteristics of the support staff. For example, to run two exam rooms in parallel, the vitals station must be set up to filter patients through from the waiting area to exam room in a timely manner. Having a vitals space that is in an awkward location or having too few staff to support patient movement through the hallways can result in exam rooms sitting vacant for periods of time or worse sitting idle with waiting patients inside. Flow diagrams, Pareto charts, spaghetti diagrams, and process time studies are all excellent continuous quality improvement tools available to help troubleshoot clinic flow issues.

It will be obvious that there is a problem; the difficulty comes with identifying the root cause and implementing and monitoring the fix. Successful improvement initiatives begin with a clear goal and an understanding of the information needed to identify and monitor measures of resolution. According to Raymond Carey, "The goal of data collection is to gain an objective view of the process under investigation and to understand how it is performing over time. The healthcare field is replete with data. Few industries collect as much data as we do in healthcare. The problem we face, therefore, is not a data problem, it is an information problem" (5).

OPERATIONAL ADAPTABILITY

Health care is an amorphous industry, one in which the physician and their support team must continuously evolve to meet the needs of their customer. Clinic operations management is complex in that it requires standardization

and structure, while remaining flexible enough to adapt as the regulatory, technologic, financial, and medical environments change. Leading change is a critical skill for physicians in light of this challenge.

"Change is a physical event so it's not surprising that many people have strong reactions to it.... To get any idea rolling, it is important to build understanding and enthusiasm. When the idea is supported by a sufficient number of key people, it takes off under its own steam, building its own sense of momentum" (6). When planning change, there are key steps that will ensure adoption by even the most reluctant support staff.

First, communicate about what is driving the change—what is the catalyst? Context helps people understand and often empathize with the change leader. Second, gain critical mass in the organization. Identify key opinion leaders who will more readily shift from neutral to supportive and allow their influence to drive peers who are resistant from their state of resistance to one of neutrality. Third, actively listen to concerns and address them consistently and persistently, allowing emotional reactions to change to subside under the limelight of good information.

Even with extensive planning and communication, there will remain those who simply will not accept change. As a change leader, be mindful that late adopters can easily drain time and resources. Identify late adopters early on and have a plan in place to address their resistance without sacrificing support for the adoptive group. Change is never easy, but will always be a part of what physicians must embrace.

A CLIMATE OF SAFETY AND QUALITY

The term *culture of safety* is typically associated with production industries like automotive manufacturing or nuclear power. "Accident-free" signs hang near construction sites, and certifications such as ISO-9000 indicate the success of assembly line industries in meeting measurable quality standards. The application of safety-oriented research is incredibly important to health care, despite its differences from a factory. Health care poses a challenge most other industries do not have: each patient is unique, so standardized processes must also adapt in consideration of each patient's needs. There is no one size fits all or mechanical assembly line. However, the benefits of standardization where applicable ensure quality and serve to reduce medical errors.

Clinic support staff must feel comfortable bringing forward matters they believe to be potential quality or safety issues. They need an open, safe forum for passing this information up to the management or physician team to proactively address. Many organizations provide an anonymous mechanism to promote honest, open feedback and solicit input from those who are on the front lines and therefore more likely to notice potential safety land mines.

The response when a medical error or safety breach does occur is also a key indicator of the culture. Health care involves many potential points of failure, and delivery of health services is a complex web of people, resources, and systems. "Errors are not synonymous with negligence. Medicine's ethos of infallibility leads, wrongly, to a culture that sees mistakes as individual problems or weaknesses and remedies them with blame and punishment. Instead people should be looking for the multiple contributing factors, which can be resolved only by improving systems" (7).

MANAGED CARE CONTRACTING

Contracting to become an in-network provider with a managed care company promotes business for the population of patients who are covered by that insurance plan. In the process of contracting, one key negotiation is the amount agreed to accept as payment in full, also called the *allowable*. Universal billing codes called Current Procedural Terminology (CPT) codes are used to both negotiate rates by procedure, as well as in the submission of claims for payment. Reimbursement for each CPT code will depend on the up front negotiation, typically phrased as a percent of Medicare reimbursement. Other contract terms include termination clauses, processes for claims submission and payment remittances, methods used to recoup overpayments or address underpayments, and length of the agreement. Small private practices are advised to seek legal counsel on all contract negotiations from an attorney experienced in health care reimbursement, and larger group practices typically employ their own contracting and legal departments to facilitate discussions with the insurance carriers and advocate for fair reimbursement for physicians work.

Overview of Negotiation Goals

Provider goals in a negotiation:	Insurance company goals in a negotiation:
Maximize payment per service provided	Minimize payment per service provided
Minimize authorization requirements for procedures, autonomy in decision-making for medical necessity	Utilization review—control procedure volumes, limit to medical necessity only
Minimize administrative burden in claims adjudication (file claims and receive payments electronically, etc.)	
Promote access to physicians for insured patients/members	

There is a delicately balanced trade-off between rates and volumes. Once the contract is signed, your role in the relationship must remain proactive and continuous. Each payer requires ongoing maintenance. Specifically, close monitoring of claims payments over time to assess whether payers are complying with the terms and agreed upon rates. Several tools in the marketplace have the capacity to electronically scrub or analyze claims payment data and identify under- and overpayments. These

tools provide the data, but reacting to it in a timely fashion is critical to your relationships and ultimately the bottom line. If payers are overpaying, they will likely request a recoupment down the road and oftentimes not at opportune moments given clinic cash flow. If they are underpaying, you must connect with your representative to identify the issue, fix it, and ensure proper payment for your services according to the agreed upon terms both retroactively and going forward. It is likely there will be errors in payment as systems on both the insurer and provider side are complicated and interwoven. Expecting payment terms to be met without constant monitoring is overly optimistic.

Key Resource: Medicare Reimbursement

Medicare allowables are public information. Rates by CPT code are published on the Centers for Medicare and Medicaid Services at https://www.cms.gov. This Web site contains up-to-date information for physicians on repayment for care of Medicare beneficiaries.

The current formula used to calculate rate of reimbursement is founded on a measure of physician productivity called a relative value unit (RVU) and on a geographic cost of living/practice adjustment called a geographic practice cost index (GPCI), as follows:

2010 Non-Facility Pricing Amount
= ([Work RVU × Work GPCI]
+ [Transitioned Non-Facility PE RVU × PE GPCI]
+ [MP RVU × MP GPCI]) × Conversion Factor (CF)

2010 Facility Pricing Amount
= ([Work RVU × Work GPCI]
+ [Transitioned Facility PE RVU × PE GPCI]
+ [MP RVU × MP GPCI]) × CF

The conversion factor for CY 2010 is $36.0846.

Specific reimbursement rates and detail on each code is available in a lookup reference on Medicare's Web site at: https://www.cms.gov/apps/physician-fee-schedule/overview.aspx.

FINANCIAL MANAGEMENT

As health care becomes increasingly complex, so too do the financial mechanisms layered beneath the practitioner in support of their clinical practice. Despite national recognition of the need to revolutionize how much our nation is spending on health care, as of 2011, the payment methodology used to reimburse physicians for their time and expertise is based on the volume of services provided. A standard value unit is applied to each procedural code available to a physician for billing (CPT Coding), and further, a dollar value is assigned to that work. As such, payment models intrinsically motivate physicians to generate the greatest volume possible. Pay for performance and value-based purchasing are new buzz words to the reimbursement scene in the early 2000s and are each an attempt to tie in quality of care in addition to volume. The idea being, rather than paying providers simply for a specific service, payers would reimburse providers based on their clinical outcomes or on measurable indicators of *effective* health care services. These systems are imperfect and exist in a variety of pilot modes across the country, but they are driving providers to pay attention to quality measures and patient population management strategies in addition to daily clinic operations. Whether or not our industry adopts these models, it is generally agreed across political platforms that the current model in the United States is unsustainable. Health care financing is convoluted and has evolved over time into a difficult to understand stratosphere of funds flows.

Where consumers (patients) are accustomed in most industries to paying for goods or services at the time they are rendered, in health care there are third-party fiscal guarantors who may be responsible for payment on the patient's behalf and most often payment from patients is not due or due several weeks after a service has been provided. The process to determine financial responsibility and pursue payment takes time, introducing days of lag between the point when a service is rendered and when it is fully paid for by either the insurance agent or patient.

Reducing this lag is a goal of any financially savvy clinic manager. There are several methods to do so, but most effective is to attempt to collect the patient portion of payment on the day of their office visit. This point of service opportunity allows the provider to make decisions about their willingness to see patients who are in debt for prior services or unwilling to resolve those balances in a timely manner. It is also a key time to educate patients about their expected out-of-pocket expense, and patients may need to make decisions about the services they receive when care is optional. Estimating the actual out-of-pocket expense for any visit is a challenge since information around the full complement of services that will be provided to a specific patient are often undefined until after a patient needs assessment is complete. Estimating as accurately as possible and practicing consistent policies for services rendered before, after, or regardless of payment is critical to establish. Typically, offices collect at a minimum the co-pay amount for their visits up front, and it is common to balance bill the coinsurance, deductible, or other cash outlay by patient statement on the back end post-adjudication of any insurance claims.

Another method to expedite payment for health care services is to file claims to the payer sources electronically. A standard, Health Insurance Portability and Accountability Act (HIPAA)-compliant file format exists to promote this mode of claims processing. It is beneficial for both the provider and insurance agent because it reduces manual intervention and labor associated with the claims adjudication process.

Patient responsibility for health care costs ebbs and flows over time. Insurance companies are shifting more out-of-pocket responsibility to patients as health care costs rise and threaten to shrink their margins. This trend has made it increasingly difficult for physicians and hospitals to accurately collect payment for their services. "The economic recession and rising unemployment—plus changing demographics and baby boomers aging into Medicare—are among the factors expected to influence health spending during 2009 to 2019. In 2009 the health share of gross domestic product is expected to have increased 1.1% points to 17.3%—the largest single-year increase since 1960. Average public spending growth rates for hospital, physician and clinical services, and prescription drugs are expected to exceed private spending growth in the first 4 years of the projections. As a result, public spending is projected to account for more than half of all US health care spending by 2012" (8). What this means to the average physician is the expectation of increased productivity, despite the inevitability that reimbursements will hit a plateau.

Enrollment in private health insurance plans is also changing the composition of guarantors responsible to pay for physician services. "Private health insurance premiums grew 1.3% in 2009, a deceleration from 3.5% growth in 2008. Benefit payment growth also slowed, from 4.4% in 2008 to 2.8% in 2009. These trends were heavily influenced by the recession as private health insurance enrollment declined. In 2009, spending for benefits increased faster than premiums, and as a result, the net cost of private health insurance (or the difference between premiums and benefits) fell to an 11.1% share of total private health insurance spending from 12.4% in 2008—a continuation of its recent decline" (9).

Given these climate changes, it is critical that physicians and health care managers work towards efficiency and contain overhead costs to the degree feasible. Again, there is a delicate balance in this task—one must continue to provide excellence in health care and promote a positive patient experience, while capturing enough revenue to sustain the practice over the long term.

CRITICAL PATIENT COMMUNICATION

Established and dependable communication pathways between providers and their patients are a requirement of any ambulatory clinic. Nurses often manage most of the triage and alleviate the provider from having to be involved in every patient care call. The key to building an effective system of triage is to empower clinic staff at the lowest common denominator to address patient needs. For example, calls from patients requesting appointments or seeking driving directions should be managed by an administrative support staff member, where a prescription refill request requires the medical expertise of a nurse to respond. Physicians may receive an escalated call if, for example, another physician is requesting a consult or advice on patient care. There must be systematic accountability built into the flow for prompt response times and follow through in meeting the caller's needs. Physicians face great competing interests for the time in their day, so building a strong team of dependable, capable staff to manage the patient care needs expands the breadth and impact of the physician's clinic day.

Patients will inevitably need to consult their physician after business hours, and a process must be in place for ensuring patient needs continue to be met during those times. Rotating a provider on call is the most common method used to promote work–life balance for physicians; having some resource available will prevent patients from defaulting to the emergency room when faced with an after-hours need.

Technology has promoted communication through electronic mail. Health care is still relatively uncharted, and physicians face liabilities on medical advice or treatment offered via e-mail. It is not yet sophisticated enough as a technology to fully assess patient status, but can be an effective tool of working with established patients to refill prescriptions or schedule follow-up appointments. While much of this is physician preference, availability of a provider by e-mail can be a major point of satisfaction for patients who are accustomed to this mode of communication for other aspects of their lives. There are CPT codes available for consults provided over e-mail; however, many insurance companies refuse to reimburse for this service. Undoubtedly, as technologies change, the potential for varying modes of communication between patients and their providers will continue to expand and evolve.

A useful tool for gauging whether a patient population is satisfied with their provider relationship and care experience is by conducting randomized patient satisfaction surveys. There are several vendors on the market that will conduct a survey by phone, e-mail, or mail; collate the responses; and provide statistical data and comment data back to their provider clients. Feedback on the physician and the patient's experience in the clinic is useful to gauge likelihood of practice growth, identify weaknesses or opportunities for improved bedside manner, and supplement face to face impressions with measurable, ongoing evaluation of care. Patients who feel confident in the abilities of their provider often demonstrate higher likelihood of compliance with treatment plans, and ultimately a solid

relationship with their caregiver can mean a healthier lifestyle through medication compliance and motivated lifestyle choices. In the end, making patients healthy is not enough—making patients happy in addition is important to a physician's success.

PATIENT PRIVACY

Clinics must be physically and operationally designed to protect patient privacy. The Health Insurance Portability and Accountability Act of 1996, or HIPAA sets national standards for the security of individual identity and health information. These guidelines are enforced by the Office of Civil Rights, and failure of a practice to comply or breach can result in serious penalties.

Key Resource: Patient Privacy Rule

Visit the U.S. Department of Health and Human Services Web site for detail on who is covered by the Privacy Rule, what information is protected, and permitted uses and disclosures (http://www.hhs.gov/ocr/privacy/).

Promote privacy in the clinic setting by following simple but often overlooked behaviors:

- Do not discuss patient cases in the hallways. Conversations can easily be overheard.
- Do not discuss patient cases with anyone other than those who need to know in order to care for the patient.
- Secure all medical records, paper and electronic. No exceptions.
- Restrict access to information systems at the appropriate levels, and track individual activity in any system containing protected health information.
- Design work spaces to promote privacy. Shade visible computer monitors, ensure patients are offered a space to carry on private or sensitive conversations with staff at registration desks and vitals stations, and insulate exam room walls to prevent noise pollution.
- Properly disclose breaches, and immediately address the security weakness in order to prevent it from impacting additional patients.

INFORMATION TECHNOLOGY

Information technology has drastically changed the way clinicians function. From the medical technologies and connectivity between them, to electronic visits and telemedicine, technologic advancement has set the stage for physicians to reach further distances to apply their skills. At the same time, technology has complicated the clinical setting by introducing a nonhuman element to patient care.

Providers often document medical record information electronically throughout a patient encounter, which can distract the physician's attention from the actual patient encounter. Balancing bedside manner with the need to efficiently and thoroughly document their treatment will be a growing challenge for physicians as technology continues to become an integral part of the health care experience.

Electronic medical records come in as many varieties as patients—there are systems designed specifically for subspecialists or generic ambulatory models that can cross multiple specialties. There are also varying degrees of connectivity. Some systems allow a community of providers to connect seamlessly to one another's medical records, with patient permission, and promote the sharing of information at the click of a button. However they are designed, their role in health care and clinic day-to-day operations is growing and critical. When implemented and used properly, the benefits of an electronic health record far outweigh the burdens. Medicare has begun tying reimbursement amounts to the use of this technology by providers through a program called Meaningful Use. The choice between paper and electronic medical charting is becoming obsolete, and drivers point towards a very near future where all medical doctors function on some degree of electronic medical records, often interconnected across practice lines.

Key Resource: Meaningful Use

Medicare is introducing financial penalties, which follow closely behind a brief period of financial incentives, for providers based on their ability to demonstrate Meaningful Use. For a full review of the program, refer to https://www.cms.gov/EHRIncentivePrograms/30_Meaningful_Use.asp.

Information technology is opening doors, not only for patient care and quality but also for management of physician practices as business entities. Making informed decisions is critical to survival in the health care industry. Regulatory and financial environments dictate constant change and require frequent reevaluation of practice viability. It is important to invest in a technology infrastructure that will allow decisions to be driven by data. There is a vast array of performance metrics, and within each metric there can also be multiple means of calculating the metric. Trending performance against both industry competitors and collaborators must be done with caution due to this variability. It is also highly recommended that trending be done against internal benchmarks, for example, reviewing the visit volumes of a practice in the current month compared to the same month prior year. This allows you to monitor both the health and viability of the practice as well as its likelihood to compete in a given market.

Below is a list of some basic key performance indicators typical of a clinical practice dashboard.

Key Measures of Practice Performance

Metric	Importance to Clinic Management
Charges	Total dollar value of services provided in a given time period. Charges are an indicator of volume of work completed by a clinician. In managed care contracts, recall that the final reimbursement amount will be the contractual allowable, not the actual charge. Always charge equal to or greater than the contractual allowable to maximize collections. Charge amounts have a greater impact on self-pay patients, unless your practice has a discount policy. Tracking charges month to month can be skewed by changes in the fee schedule.
Collection rates	Calculations for collection rates vary greatly, but the most common are Gross Collection Rate (GCR) and Net Collection Rate (NCR). GCR = Total Amount Collected/Total Amount Billed, does not account for differences in contractual allowances, subject to fluctuation with fee schedule changes which may not have corresponding impact on actual reimbursement. NCR = Total Amount Collected/Total Amount Billed—Contractual Allowances + Refunds and Overpayments. Most accurate measure of collections performance by calculating effectiveness of collecting total potential revenue.
Patient revenue	Total dollars received for services provided in a given time period. The primary source of income for most practices is fee-for-service patient care revenue; although some have other inputs such as contractual arrangements to provide consultative work or inpatient hospital coverage.
Payer mix	Patient population broken out into payer classifications. Percentages are commonly broken down into the main five to six payer classes with the remainder defined as Other. Practices often measure Medicare, Medicaid, Insured, Uninsured, and break Insured down into the top three to four coverage plans. Knowing the percent of your patient population in each category will gauge whether reimbursement rates will suffice to cover overhead.
Resource utilization	How many patients are seen per exam room per hour, or how many of the allotted clinic hours are spent providing patient care gives some measure of productivity and also use of fixed overhead on space.
Physician work relative value units (wRVU)	The relative level of time, skill, training, and intensity required to render a service. The resource-based relative value scale, developed for the Center for Medicare and Medicaid Services, assigns a relative value to each CPT code relative to all of the other CPT codes. RVUs are determined by committees of the American Medical Association. The committees' members come from all medical specialties and include representatives from other health professions, including nursing. The committees assign a relative value after hearing testimony from specialty groups on how many hours or minutes it takes to perform a procedure, the level of skill required, the level of education/training required, and the practice expense associated with a procedure. Measuring wRVU totals over time gauge the level of complexity and volume of services being provided, and are commonly used in productivity-based compensation plans for physicians.
Visit volumes	Basic count of visits attended or billed by a physician can be a gauge of patient demand for services, supply or availability of the physician, or both.

MARKETING

There will always be a need for doctors, nurses, and clinical care teams to serve patient health needs. However, success in the health care market is not a given. While demand continues to grow, in some markets supply of health care providers exceeds the community need. Marketing and attention to the public perception and understanding of your practice remain important survival tactics in the field. An investment in a marketing firm for guidance on practice name, and most effective mediums in your market will pay off. Typical mediums include

- Yellow and white pages, update both print and online directories
- Web sites—invest in both an owned and operated Web site as well as update your information found on go-to resources for the general public such as Health Grades, WebMD, and Angie's List.
- Social media networks like Facebook or Twitter
- Becoming involved in your local community through chamber of commerce memberships, local charity and volunteer work, guest speaking at conferences, and other networking business opportunities
- Outreach to referring doctor's offices through regular visits

- Direct mail campaigns or newsletters to patients and their families
- Provide opportunities for members of your local community to become engaged in your practice by offering community educational seminars or free screening days.

Any of the above incrementally or in combination will reach key audiences and promote growth. Above all, word of mouth prevails, and patients who have come to see you and had a stellar experience will be the most powerful marketing tool you have to grow your practice.

SUMMARY

This chapter introduced several fundamental skills critical to a physician's success in the medical business. While not meant to be an exhaustive manual on how practitioners can become business savvy, we have introduced the core considerations for physicians whether running a small private practice setting or becoming a member of a large physician practice plan. Business acumen comes in time and with experience, but the highlights on clinic management include

- Human resources—people are at the core of health care, and it is the most important investment of time and money you can make to develop a dependable, talented, aligned support staff. Physicians set the tone, and the attitude and citizenship of the provider will permeate all others in a clinic setting.
- Access management—making it easy for patients to get appointments will improve their satisfaction and promote relationships with the referring community.
- Clinic efficiency, remaining adaptable, and promoting a climate of safety and quality care will improve the likelihood that patients will return or recommend their physician to others.
- Financial viability of the practice hinges on managed care contracting, financial management, and accurately capturing any reimbursement for all services provided.
- Remaining available to patients for critical communication and protecting patient privacy are both a responsibility of the physician and a right of the patient.
- Information technology continues to shape health care, and it is inevitable and something that when embraced can enhance both the life of a physician and the quality of care given to patients.
- Marketing and setting oneself apart from competitors will be key in establishing an identity not as an individual physician but as a leader in the field of medicine.

Comparative Medical Systems

202

William Anthony Wood

OVERVIEW

Every year in the United States, over 40,000 people die because of lack of health insurance (1). Among industrialized democracies, only the United States fails to provide universal health coverage. According to the U.S. Census Bureau, in 2010, 49.9 million Americans—over 16% of the population—lack health insurance (2). This is an increase in the uninsured, from 2008, of several million individuals, and an increase of over one percentage point of the nation's total population. About 10% of American children under 18 were uninsured in 2009.

Among those *with* coverage, the number of people with employment-based insurance is falling. Due to recent job losses in the current economic downturn, another 2010 study by the independent Commonwealth Fund estimates that "nine million working-age adults—57 percent of people who had health insurance through a job that was lost—became uninsured in the last two years" (3). The study further notes that "an estimated 44 million people were paying off medical debt in 2010, up from 37 million in 2005," and that "4 million declared bankruptcy because of medical bills."

Most physicians are not experts on the topic of comparative medical systems. This chapter serves as an introduction, from one doctor's perspective. The topic is huge and covered in detail by peer-reviewed journals such as *Health Affairs*, along with regular commentaries in *The New England Journal of Medicine*, frequently updated books and Web sites, and in-depth reports by national and international expert organizations such as the Institute of Medicine (IOM) and the World Health Organization (WHO).

Although we do not cover everyone in the United States, we spend far more per capita than other similar countries and yet have significantly worse outcomes. Figures from 2009 from the Organisation for Economic Co-operation and Development (OECD), whose 34 countries include most of the world's wealthy industrial democracies, show total health expenditure per capita in the United States at currently nearly $8,000. This compares to an estimated $5,350 in Norway, the next highest spender, and $4,363 in neighboring Canada (4). In fact, the OECD notes that although US *government* spending on health care is less than half of *total* health care expenditures, at 47.7%,

> ...the level of health spending in the United States is so high that public (i.e., government) spending on health per capita is *greater (emphasis in original)* than in all other OECD countries, except Norway and the Netherlands. For this amount of public expenditure in the United States, government provided in 2009 insurance coverage only for the elderly and disabled people (through Medicare) and some of the poor (through Medicaid and the State Children's Health Insurance Program [SCHIP]), whereas in most other OECD countries this was enough for government to provide universal health insurance (4).

In effect, one could say that we pay enough in taxes to achieve universal coverage, but do not receive it. Other analyses point to a significantly higher percentage of total US health care spending from taxes—as much as 60%—without universal coverage (5).

Despite our outlier expenditures, our results are significantly below average, compared to similarly wealthy nations. Our average life expectancy is 78 years, compared to 80.7 years in Canada, for example (putting Canada more than 1 year higher than the OECD average, of 79.5 years, in 2009) (6). Similarly, our infant mortality is 6.5 (in 2008, latest available), which is much higher than the average in other OECD countries, of 4.4 in 2009. Our infant mortality rate is much higher than Canada's, which was 5.1 in 2007. The OECD notes that "... while life expectancy in the United States used to be 1½ year *above* the OECD average in 1960, it is now... almost 1½ year *below* the average of 79.5 years" (7) (*emphasis in original*).

There are numerous ways, aside from the standard overall statistics of life expectancy and infant mortality, to compare different countries' medical systems and outcomes. One approach looks at "deaths from treatable conditions," termed "amenable mortality." A study comparing the United States with 18 other industrialized countries, evaluating "trends in deaths considered amenable to health care before age seventy-five between 1997–98 and 2002–3," found a decline in all countries in amenable mortality over this period, averaging 17%. However, "the United States was an outlier, with a decline of only 4 percent" (8).

While our higher per capita health expenditures buy us more MRI and CT machines, on average, than other OECD countries, we have fewer doctors and hospital beds. The 2011 OECD comparison report notes that "in 2009, the United States had 2.4 practising physicians per 1,000 population, below the OECD average of 3.1." The report notes that we have 2.7 hospital beds per 1,000 population in 2007 (latest year available), lower than the OECD average of 3.5 beds in 2009. We have 34.3 CT scanners per million population in 2007 (latest year available), much higher than the OECD average of 22.1, and 25.9 MRIs per million population, "more than twice the OECD average of 12.0" (9). But more machines, and fewer doctors and hospital beds, do not equate to longer life expectancy nor lower infant mortality.

Among other participants in the field, thousands of physicians, including this author, are active in Physicians for a National Health Program (PNHP.org), a nonprofit advocacy group working for single-payer national health insurance in the United States, also termed Medicare for All. My personal perspective, based on my reading of relevant research, is that such a system would provide the most rational and cost-effective solution to the problem of the uninsured. You will make your living as an otolaryngologist via compensation from our medical system (or fragmented parts of it, as detailed below), throughout your career. If your doors are open to them, self-pay patients—a euphemism for the uninsured—will likely present themselves in your clinic every week.

THE PROBLEM: LACK OF UNIVERSAL COVERAGE IN THE UNITED STATES

Through diverse approaches, the citizens of every industrialized democracy but ours have passed universal health coverage for their populations. We are also alone in having a predominantly for-profit health insurance industry, in which insurers are private corporations that (must) generate dividends for stockholders and multimillion-dollar incomes for top executives. Here, of course, any patient "can always go to the ER," but this inadequate "safety net" approach does not constitute universal coverage.

Most otolaryngology residents see patients in the ER who have delayed seeking medical attention due to lack of health insurance. Of course, this delay often worsens their prognoses and outcomes. A study of over 60,000 laryngeal cancer patients in the National Cancer Database from 1996 to 2003 found that "individuals lacking insurance or having Medicaid are at greatest risk for presenting with advanced laryngeal cancer" (10). (The study's authors further note that "results for the Medicaid group may be influenced by the postdiagnosis enrollment of uninsured patients." Medicaid is the public insurance program for the poor, jointly funded by federal and state governments.) They comment that "in multivariate analysis, the type of health insurance remained the strongest predictor of stage at diagnosis and tumor size."

The authors of the laryngeal cancer study also looked at over 40,000 oropharyngeal cancer patients in the same national database. They found that, "after controlling for other sociodemographic characteristics, patients with advanced oropharyngeal cancer at diagnosis were more likely to be uninsured (odds ratio 1.37; 95% confidence interval 1.21–1.55)" (11). They noted that, after "controlling for covariates [patient sex, age, race, treatment facility type, zip code–based education and income categories, and U.S. Census region]," this association reached a very high statistical significance, with a value of $P < 0.0001$.

From my own residency, I remember more than one patient with laryngeal cancer who waited until experiencing acute airway compromise, after having been hoarse with odynophagia for weeks or months, before coming to the ER. These patients then usually needed a total laryngectomy for their T4 tumor. An earlier diagnosis would likely have required a less extirpative treatment. In a long-standing free annual community head and neck screening clinic conducted by the University of Michigan Department of Otolaryngology, "lack of insurance ($P = 0.05$) was a significant predictor of a lesion suspicious for malignancy" (12).

The IOM, the health arm of our National Academies, has noted for a number of years that, "for adults *without* health insurance [emphasis in original], the evidence shows: … adults are more likely to be diagnosed with later-stage cancers that are detectable by screening or by contact with a clinician who can assess worrisome symptoms" (13). The IOM physician representative who testified before Congress on its most recent report on the uninsured, Dr. John Ayanian of Harvard Medical School, noted in his testimony that "Uninsured adults are 25 percent more likely to die prematurely than insured adults overall, and with serious conditions such as heart disease, diabetes or cancer, their risk of premature death can be 40 to 50 percent higher" (14).

Lack of insurance, of course, is not the *only* factor contributing to the delay of diagnosis and treatment in seriously ill patients, including head and neck cancer patients. There are what have been termed "patient delay" factors, including vague or nonurgent-appearing symptoms. There are also "professional delay" factors, attributable to clinicians initially evaluating head and neck malignancies, in diagnosis and/or referral. These delays have been

identified for over two decades as a contributing factor in the advanced stage at which oral and oropharyngeal carcinomas are often diagnosed (15), for example.

THE SOLUTION(S)—WHAT OTHER RICH COUNTRIES DO

There are numerous different classification schema for comparing countries' medical systems. With his permission, I borrow a classification system published by the journalist and author T.R. Reid, a longtime correspondent for *The Washington Post*. He served as chief of the *Post's* Tokyo and London bureaus, and hence lived in those countries, and utilized their health systems, for extended periods of time. He recently spent over a year surveying other rich countries' health care systems, using his own stiff and painful shoulder as an entrée for a personal evaluation of these other systems. He also interviewed many physicians and policymakers, in many industrialized democracies.

He detailed his experiences and conclusions in a television documentary and a best-selling book. The documentary aired on the PBS program *Frontline*, entitled "Sick Around the World—Can the United States learn anything from the rest of the world about how to run a health care system?" (16). The countries' systems differ quite significantly, from one to the other, but they each provide universal coverage. One section of the program's website is entitled "Five Capitalist Democracies & How They Do It." His subsequent book is entitled *The Healing of Democracy: A Global Quest for Better, Cheaper, and Fairer Health Care* (17) and provides an entertaining and very readable introduction to comparative medical systems. Michael Moore's 2007 popular movie *Sicko* (18) also compared our system to other countries and includes numerous personal vignettes of American uninsured individuals.

Reid writes at length about his conversations with the Harvard economist William Hsiao, who has been involved in setting up health care systems in over a dozen countries. Hsiao (19) has coauthored a prominent textbook, *Getting Health Reform Right*, and his "team of health system analysts was commissioned by the Vermont Legislature to develop and evaluate three options for health system reform and determine which option would best achieve the stated goals" (20). His team "found that the system capable of producing the greatest potential savings and achieving universal coverage was a single-payer system."

Hsiao was very involved in setting up Taiwan's relatively new single-payer system. Reid reports that his conversations with Hsiao focused on first principles:

> "Before you can set up a health care system for any country," Hsiao told me, "you have to know that country's basic ethical values. The first question is: Do people in your country have a right to health care? If the people believe that medical care is a basic right, you design a system that means anybody who is sick can see a doctor. If a society considers medical care to be an economic commodity, then you set up a system that distributes health care based on the ability to pay. And then the poor, pretty much, are left out" (17).

As Reid notes, "all the developed countries except the United States have decided that every human has a basic right to health care." He divides health care systems into four basic models:

- The "Beveridge" model (the United Kingdom, Spain, and others)
- The "Bismarck" model (Germany, Japan, Switzerland, and others)
- The National Health Insurance model (Canada, Taiwan, and others)
- The Out-of-Pocket model

While most wealthy democracies have adopted one of the first three models exclusively, our "system" in the United States comprises parts of all four of these models, including the last, which is neither "coverage" nor a "system."

One important distinction among medical systems is often initially difficult for some Americans, including many American physicians, to grasp, in part because of imprecise rhetorical attacks on "socialized" medicine: There is a significant difference between national health *insurance*, with doctors in private practice, and a national health *system*, with doctors sometimes employed by the government. Additionally, in a universal coverage approach with *insurance*, health insurance can be single-payer, or multi-payer. The United States has a hodgepodge of different approaches, but its multi-payer (usually for-profit) *insurance* system does *not* provide universal coverage and access.

Our Medicare program is single-payer national health *insurance* program for seniors. Medicare reimburses physicians in private (or academic) practice who care for these seniors. Medicare is a "third-party payer," separate from the patient (first party) and the provider (second party). Physicians compete against one another, in the marketplace, for these senior patients, although all physicians get paid by the same government *insurance* system. In contrast, the Veterans Administration (VA) is a pure national health *system*, where the physicians are *employed* directly by the government and receive a salary for providing care to patients in that system. VA physicians do not compete among one another for patients, for example.

THE "BEVERIDGE" MODEL

The United Kingdom and a number of other industrialized democracies have health care systems in which the government is the owner of hospitals and heavily involved in doctors' compensation. Patients do not pay for care at the point of service (doctors' offices or the hospital). General taxation

provides the revenues to pay physicians' and other providers' salaries. In Britain, hospital-affiliated specialists, like surgeons, are government employees, while "general practitioners" (GPs) have their own businesses. T.R. Reid names this model after Lord William Beveridge, the aristocratic reformer who was one of the prime architects of Britain's National Health Service (NHS), which was conceived and implemented during World War II. As Reid notes, the system has "minimal paperwork and no billing." The NHS

> "cares for roughly one-fifth the population of the United States but spends only one-fifteenth of the U.S. health care bill. And yet the results are good: Britain has lower child mortality, longer healthy life spans, and better recovery rates from most major diseases than does the United States" (21).

Just as there are downsides to the lack of universal coverage in the United States, including avoidable deaths, the Beveridge model has downsides. The NHS limits medications and procedures which are covered, just as American private insurers do. Patients often have to wait for nonurgent, elective procedures. The NHS decides on these limits through an open, public process, via its National Institute for Health and Clinical Excellence, or NICE (22). Following NICE guidelines also insulates British physicians from malpractice suits. In the case of T.R. Reid's shoulder, for which an American orthopod had recommended a total arthroplasty, his GP told him that the NHS would most likely *not* pay for surgery, because he did not have a serious disability from the condition.

The NHS doesn't directly *employ* GPs in Britain, but it does provide their only source of payment. A doctor receives a capitation fee for each patient in her practice, whether the patient needs the doctor's care regularly or not. This incentivizes the doctor to provide preventative care, to reduce the number of patients with long-term sequelae from diabetes, hypertension, etc., for whom she must care. The more patients a doctor has in her practice, the higher her income. Reid notes that Britain has far more GPs than specialists, about 60%, because "the GPs in Britain generally make more money than the specialists—on average, about twice as much" (23).

THE "BISMARCK" MODEL

Before the latter part of the 19th century, "Germany" was a collection of separate principalities. Otto von Bismarck unified these fiefdoms into one empire. He also pushed Germany's parliament, the Reichstag, in 1883 to pass what is now termed "statutory health insurance (SHI)"(24). A detailed history of the evolution of the Bismarck model in Germany is available from The European Observatory on Health Systems and Policies. This institution is a collaboration of the WHO and many European governments and other institutions and publishes "health system profiles (HiTs)" on most countries in Europe and some additional countries outside of Europe, as well (e.g., Australia, Israel).

In the German system, a fixed percentage of an employee's paycheck, about 15%, goes toward membership in one of many competing, but *non*profit, health insurance plans, termed "sickness funds" (*Krankenkassen*), which the employee chooses. Employers and employees divide this expense, and joining a sickness fund is mandatory, except for the highest earners. Unlike American insurers, though, the sickness funds must accept anyone and pay any legitimate claims by providers. Elected representatives of employers and employees control the sickness funds (25), and local hospitals and doctors' organizations negotiate reimbursement fees with the funds. The sickness funds compete against one another for patients. The wealthy can "opt out" and buy private coverage from for-profit companies, which about 7% of the population chooses to do (17). The government pays the employers' share for unemployed and retired enrollees.

In 1994, with a largely private for-profit health insurance system and rising numbers of uninsured, like the current US situation, Switzerland adopted a Bismarck-type system of private nonprofit health insurance plans. The plan was approved by national referendum and took effect in 1996. Reid also details his experiences in other Bismarck-type systems, in France and Japan.

THE NATIONAL HEALTH INSURANCE MODEL

A single-payer insurance system eliminates many unnecessary expenses. First of all, the insurance system does not have to generate profits, above and beyond providing care for enrollees. Because there is no reason to exclude sick patients, the system does not have to expend resources "cherry-picking" healthy individuals. Nor does the insurance system need to spend money on marketing. Physicians and other providers do not have to employ staff to sort through different payers, claims processes, denials of coverage for appropriate services, and other similar administrative headaches.

A study of the administrative costs of health care in the United States and Canada in fiscal 1999 found total administrative costs in the United States of $1,059 per capita, compared to $307 per capita in Canada. For practitioners (e.g., readers of this chapter), administrative costs were $324 per capita in the United States versus $107 in Canada. The authors note that "Canadian physicians send virtually all bills to a single insurer" (26).

Though both Canada and Taiwan have a single-payer system, there is a notable "policy" difference between them. When Taiwan adopted a single-payer system in 1994, one of its authors, Harvard economist William Hsiao, made sure that employee and employer contributions to fund the system were termed a health insurance "premium," rather than a "tax." Canada's single-payer

system is funded through general taxation, although three provinces do charge premiums (27). Taiwan's program led to coverage for 11 million previously uninsured, and this led to a "sudden explosion of new suppliers," Hsiao notes in Reid's (28) book, with intense competition among providers, who are independent businesspeople.

WHAT WE DO—INCLUDING "OUT OF POCKET" FOR UNINSURED AND UNDERINSURED

In the United States, we have different "systems" for different classes of patients. If you are 65 or older (disabled or have end-stage renal disease), you are in a single-payer government-*financed* insurance system, and you can see your choice of any participating, competing private provider, through Medicare. If you are poor enough (criteria vary by state), you may qualify for government-financed Medicaid, though generally fewer private providers accept that third-party payer for their services, because of low reimbursement. If you are a veteran or Native American, you may qualify for a Beveridge-style government-*run* system, through the VA or the Indian Health Service.

If you have a job with good benefits, you may be able to choose from one of a number of competing Bismarck-style insurers—with the significant difference that the insurers are for-profit and hence financially interested in limiting their coverage of your claims. If, however, you are *not* poor enough to qualify for Medicaid, and your employer does *not* offer an affordable health insurance option, you will pay "out of pocket" for your health expenses. The out-of-pocket "model," or "self-pay," is of course predominant in poor countries without the resources to provide universal coverage, also.

RECENT AND ONGOING DEVELOPMENTS IN THE UNITED STATES—THE "PATIENT PROTECTION AND AFFORDABLE CARE ACT" (PPACA OR ACA) OF 2010 AND MEDICARE "REFORM"

In the spring of 2010, President Obama signed a massive new health care bill into law, attacked by critics as "Obamacare," and known more neutrally by its acronym PPACA or simply the "Affordable Care Act" (ACA). On the last day of its 2011–2012 term, a majority of the Supreme Court upheld the constitutionality of the ACA (29). The ruling is complex and incorporates several separate decisions, specifically about the mandate on individuals to purchase health insurance, and state Medicaid expansion.

The ACA's individual mandate, requiring most people and their dependents to have health insurance coverage, begins in 2014. The ACA includes a range of acceptable plans ("silver level," etc.), varying by an individual's income, subsidized for individuals through tax credits, and a tax-like penalty for noncompliance. (More details are available at the Kaiser Family Fund[KFF] website and document cited in reference 29.) The KFF analysis notes that "almost 9 in 10 non-elderly people would either satisfy the mandate automatically because they already are insured or be exempt from it."

In February 2013, Florida Republican Governor Rick Scott, who had sued to block ACA on the day of its signing by the President (one of the lawsuits that led, in conjunction with other states' actions, to the Supreme Court case), reversed his opposition to expanding Medicaid in his state (30). Numerous other Republican Governors have taken similar steps in their states. In a contrasting state-level development, in the spring of 2011 the Governor of Vermont "signed a bill… that sets Vermont on a path to creating the nation's first publicly financed health care system." (31)

The Congressional Budget Office, as of February 2013, predicts that by 2023 ACA will result in insurance coverage for an additional 27 million currently uninsured Americans, who would not otherwise have had insurance (32). Unfortunately, it also predicts that 30 million other nonelderly people will continue to remain uninsured in 2023. Legislators continue to introduce bills for a single-payer, Medicare-for-all system (33).

Prominent specialist observers of our health care system, like Jonathan Oberlander (34), a political scientist on the faculty of the School of Medicine, at the University of North Carolina at Chapel Hill, note that "there is broad agreement that the United States must slow rising health care costs." But he notes also that

> …the predominance of fiscal issues also distorts health policy by producing "reforms" that are exercises in cost shifting, not cost saving. For example, raising Medicare's eligibility age would actually increase total health care spending while shifting federal costs to employers, private health insurance, and seniors…
>
> The United States needs systemwide cost control, not budget gimmicks (34).

Canada's road to a single-payer health insurance system began with passage in one province, Saskatchewan, and perhaps a similar evolution will occur in the United States. The state legislature of our largest state, California, passed single-payer legislation in 2006 and again in 2008, which Governor Schwarzenegger subsequently vetoed (35). The father of Canada's Medicare system, Tommy Douglas, was premier of Saskatchewan when he overcame a doctors' strike in 1962 to implement the plan there. Mr. Douglas (who coincidentally is actor Kiefer Sutherland's grandfather) was chosen as "The Greatest Canadian," in a 2004 nationwide poll conducted by the Canadian Broadcasting Corporation (36).

OBSTACLES TO UNIVERSAL COVERAGE IN THE UNITED STATES

Of course, the biggest obstacle to changing the current fragmented, inadequate health care system in the United States is the political power of the for-profit health insurance industry. Aside from the dependency of federally elected officials on private campaign contributions, the US Supreme Court has ruled in January 2010 that "No sufficient governmental interest justifies limits on the political speech of nonprofit or for-profit corporations" (37). The private insurers' trade group, "America's Health Insurance Plans" (AHIP) made up of companies "providing health benefits for over 200 million Americans," is essentially silent with respect to the issue of the uninsured (38).

Wendell Potter was the head of corporate communications at the multibillion dollar health insurance giant CIGNA, before becoming a whistle-blower about the industry's dumping of sick patients to boost profits. His book, *Deadly Spin: An Insurance Company Insider Speaks Out on How Corporate PR is Killing Health Care and Deceiving Americans* (39), details the mechanics and tactics of AHIP in Washington. He testified before House and Senate committees in the run-up to the passage of ACA. He notes in his book that he warned legislators that if

> …the so-called solutions insurers were "bringing to the table"… did not include a public insurance option to compete with private insurers, it might as well be called the "Health Insurance Industry Profit Protection and Enhancement Act."

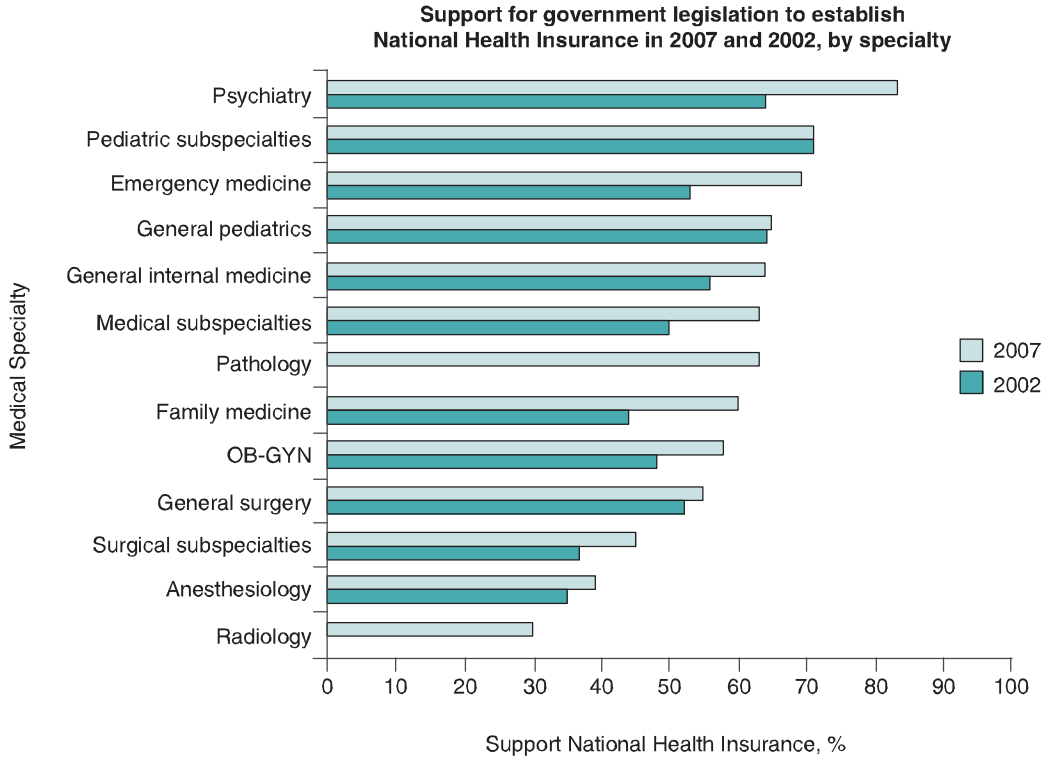
Although he somewhat reluctantly supports the law, given that some of the millions of uninsured patients will get coverage, he notes that

> …insurers will get billions of dollars in new revenues from people required by law to buy their products and billions more from the government to subsidize premiums for people who can't afford them (40).

His book is a detailed primer on how the insurance industry has used vast public relations (PR) efforts, like the focus-group tested phrase, "government takeover," successfully, in "every campaign the industry has conducted in recent decades to defeat reform efforts" (41). In his ongoing on-line coverage, he notes how the health insurance industry pursues "clear obscurity" to obfuscate the waste and expense of our for-profit, private system (42).

PHYSICIAN SUPPORT FOR NATIONAL HEALTH INSURANCE IN THE UNITED STATES

In a recent survey of over 2,000 US physicians, a majority support national health insurance (43). Only 42% support the federal government as the sole payer, in



2002 data are not available for pathology and radiology because of lack of response in those categories. OB-GYN = obstetrics and gynecology.

From Carroll AE, Ackerman RT. Support for national health insurance among U.S. physicians: 5 years later. *Ann Intern Med* 2008;148(7):566.

another survey of over 1,500 physicians from 2009, however (44). The authors of the first survey note that "more than one half of the respondents from every medical specialty supported national health insurance legislation, with the exception of respondents in surgical subspecialties, anesthesiologists, and radiologists." With respect to physician satisfaction in countries that do have universal coverage, T.R. Reid (17) notes in his medical travels that "almost every doctor in almost every country…complains that he isn't paid enough for his hard work."

ALL HEALTH CARE SYSTEMS "RATION" CARE

All medical care exists in a framework of virtually unlimited demand from patients, constrained by a limited supply by providers and institutions. Any such phenomenon requires "rationing," though countries use different methods to distribute this limited resource. In the United States, we ration by economic status: If you have a good job with benefits, or fall into one of the patchwork government systems, you have coverage. A former British health minister, John Reid, describes rationing in the UK's Beveridge system with the phrase, "We cover everybody, but we don't cover everything" (45). Canada has waiting lists for many elective surgeries, but has better overall health outcomes than the United States. No other country, though, arranges its health system to provide a profit to investors and disproportionate salaries to insurance company executives, and squeezes patients to generate those funds, as we do.

The prominent health care economist Uwe Reinhardt (46), Professor of Political Economy at Princeton, notes that "The price system constitutes just one of many ways to ration scarce resources." He details one vignette of price rationing, which leads to many physicians not treating patients on Medicaid:

> Consider the legislators of my home state, New Jersey, who apparently think nothing of limiting compensation to a pediatrician to $30 for a Medicaid office visit, while bestowing upon themselves insurance that pays that same pediatrician $90 or more for treating their children.

He later notes that

> It is not clear to me on what ethical or scientific basis one could judge this (US) approach to rationing health care to be more "efficient" than rationing by queue….
>
> As already suggested, few Canadians would consider it ethically acceptable to pay a pediatrician much less for treating a poor child than for treating a rich child (46).

I urge readers, particularly residents, to become more than lay people, when it comes to the system by which you will make your living.

HIGHLIGHTS

- The United States is the only industrialized democracy without a system of universal health care.
- The United States spends far more per capita on health care than other rich countries, with worse health outcomes—for example, higher infant mortality and shorter average life expectancy. This results in large part from far higher administrative costs, generated by private, for-profit health insurance.
- Lack of health insurance in the United States leads to avoidable deaths and advanced disease at presentation. For example, laryngeal and oropharyngeal tumor stage is more likely to be advanced at time of diagnosis, in patients without health insurance.
- Other industrialized democracies have a variety of universal health care systems, including the "Beveridge" model of a National Health Service (e.g., the NHS in the United Kingdom), the "Bismarck" model of nonprofit cooperative insurance funds with physicians in private practice (e.g., Germany), and single-payer National Health Insurance (e.g., Canada's Medicare system), also with physicians in private practice.
- The United States has different systems for different populations: National Health Insurance for seniors (our Medicare), a Beveridge system for veterans and Native Americans (the VA and Indian Health Service), for-profit private insurance for some employees, and "self-pay" (no insurance) for many other individuals.
- The United States is the only industrialized democracy with a predominantly private, for-profit insurance industry. These companies must generate a return for stockholders and high salaries for executives, leading to necessary rationing of patient care on the basis of expanding company profit.
- The ACA of 2010 will insure tens of millions of currently uninsured Americans, but will still leave tens of millions of others uninsured.
- The primary obstacle to universal coverage is the stranglehold on reform exercised by the for-profit private insurance industry, through deceptive public relations strategies, multimillion-dollar lobbying campaigns, and privately financed elections of Congress.

Effective Education in Medical Practice

203

John M. Schweinfurth

Graduation from a residency training program and entry into surgical practice represents an abrupt and often permanent change in learning styles. Professors are fond of telling the graduate, "This is just the beginning of your education, not the end." The divide is dramatic. Nothing in didactic form approaches the learning experience of the real world, where there is no textbook, no lesson plan, and no instructor to fall back on. Indeed, many early decisions are based on the teacher's transplanted wisdom. Often the transition is abrupt; the educational process up to graduation is based on a teacher-directed model of learning for which there is no direct continuity in practice. Currently, there are multiple, instructor-led resources for long-term learning including opportunities for continuing medical education (CME) from annual national and regional professional meetings, home study courses, audio digests, and online reviews.

This chapter, however, is not about formal, teacher-directed learning activities such as lectures and CME. The reality is that instructor-led CME activity, while valuable, represents not only an artificial learning environment but a relatively ineffective one at that (1). Active engagement in self-planned learning activities tends to be more effective than the passive learning, which commonly characterizes formal CME. The vast majority of postgraduate, or lifetime, learning is problem specific and occurs in the context of real experience: the clinic, on an Internet search engine at night, or over the phone with a colleague; those conversations that invariably begin, "I have this patient…."

Lifetime learning involves finding and implementing solutions to everyday problems encountered in the clinic, in the emergency room, in the operating room, and on the wards. The process by which much of this education occurs is via *self-directed learning* (SDL). According to Gibbons, a paradigm shift in instruction is "teaching students to challenge themselves to pursue activities that arise from their own experiences, employing their own emerging styles to find patterns of meaning and processes of productivity that lead them to a high level of achievement and fulfillment. The prime imperative… is not to enhance teacher-directed learning, but to develop a more student-directed model" (2).

WHAT IS SELF-DIRECTED LEARNING?

Initially described by Malcolm Knowles, in its broadest meaning "self-directed learning" is a process

> "… in which individuals take the initiative… in diagnosing their learning needs, formulating learning goals, identifying human and material resources for learning, choosing and implementing appropriate learning strategies, and evaluating learning outcomes" (3).

Knowles argues that proactive learners learn more things better than do passive, or "reactive," learners. They enter into learning purposefully with greater motivation and better long-term retention. Finally, because of rapid changes in our understanding of the world, it is no longer realistic to define education as the transmission of static knowledge but to develop instead skills of inquiry.

Hammond and Collins (4) describe SDL as "a process in which learners take the initiative, with the support and collaboration of others. For increasing self- and social awareness; critically analyzing and reflecting on their situations; diagnosing their learning needs with specific reference to competencies they have helped identify; formulating socially and personally relevant learning goals; identifying human and material resources for learning; choosing and implementing appropriate learning strategies; and reflecting on and evaluating their learning." This humanistic characterization of SDL implies a sense of social awareness, self-actualization, and the acceptance of personal responsibility for one's own learning.

TABLE 203.1 SKILLS AND COMPETENCIES OF THE LIFELONG LEARNER

The lifelong learner would:
- Be methodical and disciplined
- Be logical and analytical
- Be reflective and self-aware
- Demonstrate curiosity, openness, and motivation
- Be flexible
- Be interdependent and interpersonally competent
- Be persistent and responsible
- Be venturesome and creative
- Show confidence and have a positive self-concept
- Be independent and self-sufficient
- Have developed information-seeking and retrieval skills
- Have developed knowledge about, and skill at, learning generally
- Develop and use defensible criteria for evaluating learning

The acquisition of SDL is a complex process, involving numerous skills and competencies relied upon to complete challenges such as medical school and residency. Unlike the classroom setting, where the emphasis is on mastery of content, SDL emphasizes *personal* action taken to become more productive. Testing is no longer an issue, but performance certainly is. Many authors have identified SDL as essential to continuing education efforts in adults (5,6).

Not everyone is ready to accomplish SDL, however; this is because certain traits are essential for becoming a successful, productive individual. Candy (7) synthesized an essential character list from over 100 such traits (Table 203.1).

Barrows called for the application of SDL in medical education because "the curricula of many medical schools put too heavy an emphasis on memorization of facts and little stress on problem solving or self-directed study skills necessary for the practice of medicine. Problem-based SDL is a teaching–learning method specifically designed to emphasize these skills and to increase the retention of facts and their recall in the clinical situation" (8). Generally, SDL is not limited to specific settings but can occur as a part of any process and include formal learning activities as well. Among Tough's factors are three common patterns in independent study: a specified learning need, curiosity, and a general desire to learn (9). Houle (10) described three groups of adult learners: goal oriented, activity oriented, and learning oriented based on their immediate educational needs, not necessarily on individual learning styles. Of these, most practicing physicians clearly fall into the first category, as they embark on a learning project to acquire new procedural skills, to become familiar with new medications, or updates in coding and reimbursement schedules, for example. Activity-oriented learners participate for social interaction and learning-oriented for the sake of knowledge itself.

THE CHALLENGE MODEL OF SELF-DIRECTED LEARNING

Possibly the most influential essay on SDL is *The Walkabout* by Maurice Gibbons published in the 1974 edition of the Phi Delta Kappan. At the heart of the essay is the movie of two children lost in the desert wilderness of the Australian outback. Facing certain death, the two are found and cared for by a young aborigine on his walkabout, a 6-month long endurance test during which he must survive alone in the wilderness and return to his tribe an adult. Gibbons surveys the ramifications of the story from a societal standpoint:

"The movie is a haunting comment on education. What I find most provocative is the stark contrast between the aborigine's walkabout experience and the test of adolescent's readiness for adulthood in our own society. The young native faces a severe but extremely appropriate trial, one in which he must demonstrate the knowledge and skills necessary to make him a contributor to the tribe rather than a drain on its meager resources. By contrast, the young North American is faced with written examinations that test skills very far removed from the actual experience he will have in real life. He solves familiar theoretical problems; he does not apply what he knows in strange but real situations…. His preparation is primarily for the mastery of content and skills in the disciplines and has little to do with reaching maturity, achieving adulthood, or developing fully as a person."

The walkabout model is quite applicable to the learning required by the practicing physician. First of all, it should be experiential and the experience should be "hands-on." Second, it should be a challenge that extends the capacities of the learner. Third, it should be a challenge specific to or, better, designed by the learner. A productive learning experience depends on the learner's ability to make appropriate choices, but in most teacher-directed situations the student is not called upon to make any meaningful choices. "The test of the walkabout, and of life, is not what (the learner) can do under a teacher's direction, but what the teacher has enabled him to decide and to do on his own" (Gibbons, 1974). Most importantly, the trial should be an important learning experience in itself and should involve not only the demonstration of the student's knowledge and skill but also his or her self-awareness, flexibility, and nature as a person.

THE "CHANGE" MODEL

Fox et al. (11) developed a model of learning and change based on 700 incidents in over 300 physicians. The authors found that the most common forces for change were professional: a general desire for competence or the perception of a changing clinical environment. Once a need for change is identified, the physician develops an image of how the practice would appear following the change.

Information is gathered to help analyze the gap between existing skills and those necessary to complete the change. It is the process of analyzing and describing the gap that provides the jumping-off point for planning, development, implementation, and assessing learning activities. The process of change involves three stages: preparing to change, making the change, and sustaining the change (12).

LEARNING THROUGH EXPERIENCE

The process of learning through experience has been described in Kolb's (13) experiential learning cycle.

1. *Concrete experience*: In the first stage, a physician may encounter an unexpected situation that differs from expected practice, for example, a complaint of hoarseness with a normal-appearing larynx.
2. *Reflective observation*: Following the encounter, the physician reflects on the experience, performs an Internet search, consults with a colleague, or perhaps takes no further action.
3. *Abstract conceptualization*: The physician combines the results of reflection with any new knowledge gained to conceive of a possible new approach, which would theoretically encompass the problem, in this case a neurologic disorder such as spasmodic dysphonia or vocal scarring.
4. *Active experimentation*: A new approach may be taken. In the present example, a videostroboscopy might be performed or a new diagnosis considered and tested. The experience with the new approach, for example, findings on videostroboscopy, immediately lead to a new concrete experience and the cycle begins anew.

Kolb's cycle provides an excellent model for conceptualizing the learning process a practitioner might undergo as a result of clinical challenges encountered on a regular basis. There is an abundance of adult learning research that supports the role of experience and reflection in continuing education (14–18). In reality, the process is likely to be more dynamic, complex, and interrupted with fits and starts, dead ends, misinterpreted experiences, and incorrect conclusions. An awareness of the process will assist the learner and educator in designing and promoting educational experiences, which allow for each stage to occur and mature.

PROMOTING SELF-DIRECTED LEARNING

Although an internal motivation for learning is more powerful and enduring than external forces, near-term goals such as recertification and renewal of medical licenses and hospital privileges will be the order of the day when time is limited, as is always the case. Factors that may both facilitate and combine these processes will ultimately be more productive and satisfying to the learners and to professional boards and licensing bodies. Specialty literature, national and regional conferences, and other CME activities may help learners identify gaps between needed skills and current capabilities as well as help learners to visualize an image of change to see how it might look to do something differently.

Computerized learning modules and portfolio projects may potentially bridge these knowledge gaps. Similar to a teacher-directed learning experience, computer modules may serve to drive Kolb's learning cycle by providing prompts and asking questions that require reflection or application of new knowledge. Online searches offer access to very specific sources of knowledge not readily available in texts. Portfolio projects can serve to document the SDL process, both for refinement and potentially for CME credit or recertification. A portfolio is a purposeful collection of work that chronicles learning needs, goals, efforts, progress, and achievements. These can take the shape of a collection of loose papers or a sophisticated interactive computer-based module. Presented to a professional or licensing board, they represent the comprehensive learning efforts of the individual as opposed to strict learning outcomes as obtained through exams. Portfolios, consequently, provide both instruction and assessment simultaneously. Unlike standardized tests, portfolios are as unique as their creators and can be used to discover the needs of individual learners and their evolution over time, as opposed to legislating knowledge from a central authority.

Identifying Needs

Once a strong professional identity has formed, usually after the first year of training, resident learning may be described in a manner similar to that of practicing physicians by the "change model" of Fox et al. (11). In interviews with over 300 practicing physicians, the authors found that the desire to learn and change can come from professional, personal, and social reasons. In their experience, the most common reasons for change included a desire for general competence or the recognition of a changing practice environment (such as competition, improved patient self-education, and access to the Internet). Physicians respond to areas of deficient knowledge by referring complex patients, discussions with colleagues, and consultation of the literature (14). These behaviors are typically stimulated by perceived deficiencies from caring for a particular patient, discussion, or reading. However, these deficiencies are often subjective and may not accurately reflect actual needs. Objective needs assessment is therefore needed in order to provide a more realistic image of knowledge gaps. Systematic assessments, such as performance audits and outcomes measures; patient care benchmarks; billing; and documentation audits are examples of measures that provide objective measures. Other examples include independently reviewed portfolio projects and written or computerized tests and problem-based scenarios. Regardless of

the assessment strategy used, it is important to allow the physician to develop a self-monitoring strategy rather than to merely respond to external events.

Computerized Self-directed Learning Modules

Adult learning theory, including Kolb's cycle and the principles of SDL, depends on the developments of practical tools that help individuals take charge of their learning and apply the theory to their own practice. As the personal computer and the Internet have enjoyed growing widespread use among physicians as an essential resource, the potential for their application in CME has also expanded. Although the full potential of computerized SDL has not yet been reached, several models are available in fields other than otolaryngology, which serve as examples of potential structured programs.

The Maintenance of Competence (MOCOMP) program is designed to encourage specialists to take charge of their own CME efforts (19). The program has three components: (a) a credit system to promote production of high-quality, practice-based, educational programs; (b) a self-directed CME plan designed to motivate individual specialists to record and critically appraise their CME activities; and (c) an annual, personalized CME profile. There are many ways that physicians obtain information, that is, reading, consultations, rounds, research, etc., but these activities are too numerous to record on a regular basis and rarely lead to a change in practice. This information screening is defined as "General Professional Activity" in the revised MOCOMP program and consists of scanning the professional environment for new ideas. Occasionally information does capture the interest of the specialist who might then explore the area in more detail, known as "In-Depth Review." These activities are focused and goal oriented and should lead to one of the following outcomes after completion (20):

1. I will modify my practice.
2. I will wait for further information before I modify my practice.
3. I see no need to modify my practice.

The Computerized Evaluative Learning Tool (CELT) is based on the adult learning principles that learning should acknowledge prior experience, allow reflection, be participative, provide ownership, and be self-directed (21). The users enter data under four menus depending on whether they have a specific learning need, wish to apply new knowledge, or learn from an event to reduce future risk and/or to analyze and learn from the emotions the event caused. The four menus are as follows:

1. *Educational need*: The user starts with a learning need and the program takes them through meeting the need and then applying the learning in practice.
2. *Educational event*: The user recollects a specific learning point and is guided to apply it in practice.
3. *Emotional response*: This allows learning from an emotional experience to take place and enables a change in future behavior.
4. *Significant event analysis*: This allows learning to take place following a significant event in the workplace and enables the user to make changes to minimize the risk of a subsequent event.

CELT provides a learning structure to enable physicians to recognize and document that learning has taken place, to be specific about what has been learned through reflection, and then, if appropriate, to act on the learning and apply it in practice.

Portfolio Projects as a Model for Future Recertification

The computer models described above provide not only a framework for SDL but documentation of the process, which becomes an individual portfolio. Indeed, this process and the accompanying documentation could potentially be used not only for CME credits but for recertification itself as discussed previously. The Royal College of Physicians and Surgeons of Canada and several of the specialty societies, including the Canadian Anesthetists' Society, have developed the MOCOMP project as part of the recertification process. The philosophy of MOCOMP is to develop a comprehensive CME strategy, which will motivate specialists to continuously update their clinical practice.

Whether through the use of a software-based SDL computer module or simply documentation on the computer, the use of portfolio projects as part of the recertification process benefits physicians in several ways. First, it encourages and formalizes the process of SDL. It is likely that the documentation will encourage both an increase in quality of the process and product as well as the learning experience. Second, it encourages familiarity and therefore skill with the process so that each time SDL is initiated with less reservation. Finally, and most importantly, the physician can be rewarded with specialty CME hours or potentially with partial recertification credit depending on acceptance from accreditation bodies.

INTRODUCTION OF SDL IN THE UNDERGRADUATE CURRICULUM

The origins of Kolb's work may be traced back to a famous dictum of Confucius circa 450 BC: "Tell me, and I will forget. Show me, and I may remember. Involve me, and I will understand." As discussed at the beginning of the chapter, the transition from teacher-led to learner-directed activity is unnecessarily abrupt. Given the rapid changes in medical knowledge and practice, the need to keep abreast of the field is the one constant. But are graduates really ready for SDL? Seemingly not, as residency prepares them for learning passively from lectures and actively only from studying

textbooks, board preparation materials, and journals. These activities are directed toward mastery of a body of knowledge. As described previously, real-world learning is typically problem based, not comprehensive. So, it seems intuitive that incorporation of problem-based learning in residency is more preparatory for SDL than simply memorizing a body of knowledge.

The goals of teaching as described by Isaacs (22) are (a) to arouse and keep students' interest, (b) to give facts and details, (c) to make students think critically about the subject, and (d) to prepare students for independent studies by demonstration of problem solving and professional reasoning. Isaacs notes, however, that only two of these purposes are well suited to didactic lectures. The problem then is how to organize lecture material so that individual student's learning needs are better addressed. Gibbs (23) suggests that lecture sessions contain a variety of activities designed to stimulate individual students to think including small group discussion, working problems during lecture time, questions included in the lecture, and quizzes at the end of lecture, among others. Possibilities considered include standard interactive lecturing, facilitated discussion, brainstorming, small group activities, problem solving, competitive large group exercises, and the use of illustrative cliff hanger and incident cases. Kell and Van Deursen (24) identified a preference toward teacher-directed learning in average age learners and student-directed in mature learners. The differences in learning preference persisted 6 months after graduation. The results suggest that mature students enter the course with skills that equip them to be more flexible in their learning, less dependent on instructor direction, and more self-reliant. Although further research is needed to identify which life skills are practiced by mature students and those that would promote SDL if encouraged in younger students, activities that promote involvement and active learning would be expected to promote SDL in later life (25).

CONCLUSION

This chapter is intended as a primer and not a comprehensive discourse on SDL and its application in CME. It is every teacher's responsibility to realize the impact of their teaching on their learners so that the learners' natural tendency for self-direction, displayed in their personal lives, can be transferred to their educational and working environments (26). Similarly, national specialty boards and associations, licensing boards, and governing bodies should recognize the importance of continuous SDL motivated by an internal desire to improve rather than as merely a reaction to external mandates.

204 Medical Informatics and Databases

John C. Sok *Richard K. McHugh*

Our ability to obtain medical information has increased exponentially with public access to the Internet (1). As more hospitals and health care systems transition to the use of electronic health records (EHRs), the potential for machine-searchable clinical data significantly increases. EHRs store various forms of data including clinical diagnosis, drug prescriptions, treatment interventions, testing, and other associated medical records. We have more clinical data available to us now than at any other time in history, and the volume only continues to increase. This chapter describes the emerging field of medical informatics in otolaryngology and serves as an introduction to data mining and searchable clinical databases.

Collections of clinical data comprise various forms of databases. Smaller studies are amenable to researcher-performed manual searches through primary data. However, given the increasing volume and complexity of the data, medical informatics will become even more essential when performing clinical studies. Data mining of clinical databases also has the potential to find associations that would not otherwise be uncovered by traditional manual search and analyses. Furthermore, genomics and other translational forms of data are adding more complexity to clinical databases. This volume and variety of data is likely to continue to increase and become more complex as we shift from analysis of static targets (e.g., DNA, RNA, protein sequences) to dynamic targets (e.g., transcription, expression, metabolism, and genomics). Although daunting, such data present us with unparalleled opportunities. The medical informatics required to perform successful analyses of large clinical databases entails the combination of biostatistics and computational biology, among many other disciplines. Here we provide a framework to understand and apply medical informatics to clinical and translational studies in otolaryngology.

INTRODUCTION TO CLINICAL DATABASES

A database represents any organized collection of information, usually in digital form. There are several types of databases utilized in clinical medicine as reviewed by Harrison and Aller in 2008 (2). Larger regional and national data may be obtained from insurance or care provider claims data, single or cooperative provider repositories, or public health and government databases. Unfortunately, insurance databases and most government databases are not designed to record complete clinical records. Furthermore, such databases may be greatly impacted by selection, analysis, and interpretation biases (3). For instance, billing codes may be used to identify a study group. However, such codes may have been submitted as "rule out" diagnoses and may not represent the actual diagnosis. Moreover, the choice of codes utilized may be influenced by financial incentives. Further, only billed interventions may be listed such that the study lacks a complete clinical record of observations due to nonbillable interventions being excluded. Therefore, databases comprised of insurance claims data or similarly compiled data may be used to draw broad population-based associations but are not suitable for higher complexity clinical questions.

An individual clinician or clinical service often creates clinical databases composed of a series of patients with a common disease process, symptom, or treatment paradigm. Although this type of data is more precise and prone to fewer selection errors than insurance claims data, the population study size and size of the geographic area are generally small. The creation of such databases is usually under the auspices of a single Institutional Review Board (IRB) approval and designed to study a focused set of questions. These databases are usually small enough to facilitate manual analyses performed by one or more researchers.

Unfortunately, databases created in this format are not broadly applicable to other clinical data mining queries.

Although there still remains some resistance by physicians to adopt EHR systems, EHRs are becoming more prevalent (4). In February 2009, US Congress enacted into law the Health Information Technology for Economic and Clinical Health (HITECH) Act, which implemented new policies to induce adoption and "meaningful use" of EHRs by hospitals and physicians. Therefore, the American Academy of Otolaryngology—Head and Neck Surgery Medical Informatics Committee recently published formal recommendations and guidelines to encourage the adoption of EHRs (5). EHRs yield a wealth of clinical data. When planning a study that uses EHRs, the specific types of data and analyses should be predetermined prior to beginning the study. For instance, the population under study should be definable such that conclusions have wide applicability. Other factors to consider include age, gender, interventions, follow-up, and others. These factors produce many types of data. All of the temporal data and some laboratory results may be represented by numerical data. Binary coding may be used for gender, qualitative laboratory results, and status changes such as recurrence of a disease. Staging systems, ICD-9, and CPT numbers yield commonly accepted codes. However, a significant proportion of clinical data is textual and is in analog form derived from various health practitioner notes including clinic and operative notes, or descriptive reports from imaging studies.

Outcome measures, narrative text, and other textual data are most cumbersome to evaluate. It requires a researcher to manually evaluate each case individually in order to ascertain the data and often presents additional challenges related to the analysis of such data. Furthermore, text-based data sets are generally not conducive to data mining analyses for several reasons (6). First, EHRs record a significant portion of data in nonsearchable textual form. Nonsearchable text-based data need to either be transferred to a data warehouse as coded and searchable data, or a text-based search engine capable of utilizing the EHR directly must be in place. Second, there are a multitude of incompatible EHR systems. The differences in these systems limit one's ability to merge the data for collaborative efforts. Natural language processing presents a possible solution for recording and analyzing textual data, and it has been proven to have had at least limited success for data mining in the field of Allergy (7).

The Veterans Administration (VA) manages a nationwide system of EHRs. This is perhaps the best documentation of EHR models, and it has been noted to have significant advantages and disadvantages (8). The VA EHR system is known as the Veterans Health Information Systems and Technology Architecture, or VistA. The greatest advantage of the VA EHR database is the immense volume of available clinical data. However, at this time, its data searches are not perfect and can produce duplicative results, requiring manual review and thereby creating inefficiencies. There are plans to update VistA to improve its data mining capabilities and to support evidence-based medicine studies.

Since EHR databases are difficult to utilize due to textual data and inefficient search strategies that were not designed to facilitate clinical studies, researchers have created data warehouses (6). Data warehouses are comprised of EHR data that is coded, structured, and inclusive of all personal patient information deidentified for Health Insurance Portability and Accountability Act (HIPAA) of 1996 compliance. The software for such a warehouse is designed to support clinical databases studies and data mining. As such, data warehouses represent a powerful source for associative clinical studies. However, the cost to create and maintain a data warehouse is substantial. Usage of such clinical data framework for research on a population at a national level has been examined for the United States (9).

Regardless of the source, data must be accurate and standardized in order to be useful in any study. Therefore, the first step to answering a research question that proposes to query a database should be to ensure that the data is of acceptable quality for such analysis. Likewise, the first step in creating a database should be to set universal standards for how data are recorded to maintain or increase relevance for studies.

BASICS OF CLINICAL DATABASE ANALYSES

As clinical databases grow to provide increased statistical power and become representative of the overall population, the methods to perform clinical analysis of these databases grow beyond the limit of manual search strategies. Medical informatics seeks to create and utilize robust computational methods in database studies. The basic principles of clinical trial design and statistical analyses are the foundation for medical informatics. Although the details of these principles are beyond the scope of this chapter, many reviews on this topics have been published (3,10–12). It should be noted that nonrandomized or noncontrolled data are not able to establish causality. However, population-based correlative studies may be extremely powerful at revealing associations and limiting bias and may be applicable to situations in which a randomized, controlled trial could not otherwise be performed.

Unfortunately, studies that are not randomized and controlled are more likely to be predisposed to bias. Bias entails random, systematic, or intentional disagreement between the results and the true occurrence. Bias may influence any part of a clinical study including population accrual, data collection, analysis, or interpretation. Formulation of any clinical study should include efforts to understand and limit potential biases (3).

Data mining involves "extraction of implicit, previously unknown, and potentially useful information" through mathematical analysis (13). Therefore, through pattern discovery, clustering, and other methods, it may reveal

clinically significant associations. By definition, data mining is different from the standard statistical analyses used in clinical studies. Brown and Harrison provide encompassing reviews of data mining and the complex analyses possible (14,15). As with any database study, data mining requires complete, accurate, structured, and coded data to perform adequate calculations. Unfortunately, medical data are perhaps the most difficult on which to perform data mining due to multiple factors including high dimensionality, heterogeneity, imprecision, and temporal patterns (15). A number of premade tools for data mining exist. "Open-source" tools created in a collaborative, nonprofit, and expandable manner have distinct advantages over commercial data mining software packages (16). Specific usage of data mining tools is beyond the scope of this introduction, and collaboration with a statistician familiar with these methods is recommended.

CLINICAL DATABASE APPLICATIONS

Clinical databases may take many forms based on the type of data, structure, and other features (see Table 204.1). Here we describe the steps to complete three types of clinical study based on specific databases. First, we describe the meta-analysis study using the PubMed and other literature databases, which is a commonly employed study for clinical research. Second, we describe the Surveillance Epidemiology and End Results (SEER) database for cancer population studies. Lastly, we describe the utility of the VA EHR VistA. A published study relating to laryngeal cancer is utilized for each database study example. Each example study may be obtained for in-depth information and assist extrapolation to similar types of studies and databases. Although software-based search and analysis has become more commonplace, these studies required manual review by a researcher to some degree.

PubMed and Literature Databases (e.g., Meta-Analyses)

The PubMed database is a free resource that was developed and is maintained by the National Center for Biotechnology Information (NCBI). It is one of the most commonly accessed literature databases in clinical medicine and basic science research. The PubMed database from the National Institute for Health (NIH) and National Library of Medicine (NLM) comprises almost 21 million citations for biomedical literature. It includes all citations from MEDLINE, life science journals, NLM, as well as older citations from the print version of Index Medicus going back to1951. It also includes some new citations prior to publication and indexing in MEDLINE. For most clinical researchers, PubMed provides the majority of the data to perform meta-analyses and practice evidence-based medicine. Searching on PubMed is facilitated through several key concepts. Searches are best performed for concepts while being as specific as possible. By using several conceptual words, a search may be narrowed. Searching for English language only or review articles may further narrow a search. Combining searches may be useful to understanding the volume of literature available for topics. For instance, a search for "chemotherapy" returns over 2 million citations. A second search for "laryngeal cancer" returns just over 25,000 citations. Next, combining these searches (e.g., searching for both "chemotherapy" *and* "laryngeal cancer") returns just over 2,300 citations.

TABLE 204.1 COMMON DATABASES

Database	Type of Data	Type of Studies	References
Cochrane Collaboration	In-depth clinical reviews	Systematic review Meta-analysis RevMan statistical analysis software	www.cochrane.org
ENSEMBL	Genomic sequences	Sequence comparison	www.ensembl.org
NCCN	Cancer registries Medical records		
Nucleotide/BLAST (NCBI)	DNA sequences Protein sequences	Sequence comparison	www.ncbi.nlm.nih.gov/nuccore
PubMed (NCBI)	Compilation of biomedical citations from MEDLINE, life science journals, and online books		www.ncbi.nlm.nih.gov/pubmed/
Research Portfolio Online Reporting Tools (RePORT)	Reports, data, and analysis of NIH research activities	Ongoing NIH research activities	www.report.nih.gov/
Surveillance Epidemiology and End Results (SEER)	US cancer statistics	Population trends	www.seer.cancer.gov/
VA	EMR Million Veteran Program		www.research.va.gov/

Although not exact, this combination gives the impression that approximately 10% of the literature on laryngeal cancer involves chemotherapeutic treatments. Or approximately 0.1% of the literature concerning chemotherapy is also concerned with laryngeal cancer. Finally, by registering and opening an individual account with NCBI, a researcher may save the searches for future study. There are also other methods used to manipulate searches, and an online training tutorial can be found on PubMed (http://www.nlm.nih.gov/bsd/disted/pubmed.html).

The Cochrane Collaboration is a nonprofit international organization established in 1993 and designed to support best evidence-based comprehensive reviews of treatment modalities (www.cochrane.org) (17). Submission of a review begins with registering your topic in order to prevent duplication and to judge the appropriateness of the topic. The process of developing a Cochrane review topic is undertaken by a team with expertise that covers both the topic and the statistics required for analysis. Such reviews require data mining literature, most commonly utilizing PubMed. Most Cochrane reviews analyze randomized control studies and study interventions or diagnostic tests. Therefore, a Cochrane Review represents both a powerful resource for data mining results and a database of evidence-based reviews. It is perhaps the pinnacle of evidence-based medicine studies utilizing other literature databases to perform systematic reviews.

A meta-analysis involves statistical analysis from a compilation of multiple related studies. Features extracted from each study must include similarities in the type of data and population such that the data may be grouped and reanalyzed. By employing multiple studies, power may be increased in the analysis of a potential clinical result. The use of multiple studies seeks to reduce the effect of systematic error in most cases. However, publication bias may occur due to the increased probability that research with statistically significant results will be published, while studies without significant results are less likely to be published. Therefore, a meta-analysis involving multiple published studies may be more affected by publication bias. A funnel plot may demonstrate that publication bias is minimized.

Performing a meta-analysis requires a stepwise approach (see Table 204.2) and, often, the assistance of a biostatistician. Resources required for performing a comprehensive meta-analysis is detailed in literature (17,18). A meta-analysis begins with a research question or a clearly stated hypothesis. Often, both published and unpublished studies are incorporated into the meta-analysis. "Gray literature" includes studies that are not available in the standard search engines, such as unpublished results, abstracts, conference proceedings, graduate theses, and book chapters (18). In some instances, the incorporation of gray literature improves the quality of the meta-analysis as it may serve to reduce publication bias (19). However, gray literature is often not peer reviewed and tends to be smaller studies of generally lower statistical power. To obtain homogenous data between studies, definable criteria such as age, sex, tumor site, stage, performance status, treatment allocated, date of randomization, date and site of first recurrence, date of second primary cancer, and cause of death are collected. Survival status and latest follow-up data are also collected. Often, each study is statistically analyzed independently for internal consistency.

TABLE 204.2 STEPS IN COMPLETING A META-ANALYSIS

Step No.	Action	Further Information
1	Formulate a hypothesis.	This is the basic research question(s).
2	Define the search parameters (database).	Type(s) of studies to review? What years? Follow-up? What database(s) will be searched? Will gray literature be included?
3	Define the inclusion criteria (study).	Create a grading system for literature based on inclusion criteria.
4	Perform the search.	This will identify specific literature that fits the criteria and provide a quality grade for each. If fewer than expected studies are included, consider modifying the hypothesis to fit available literature.
5	Analyze the included literature.	Calculate effect sizes. Code moderating variables. Summary estimate of effect (with 95% confidence interval) Test of homogeneity Provide a descriptive analysis.
6	Interpret the results.	Relate the results to the hypothesis Consider possible mechanism(s) Consider limitations (appropriateness of data to hypothesis, type and quality of studies, power)
7	Future directions	Consider future directions for further research.

The analyzed data then undergo interpretation and discussion. It is common to compare the result to that of other prominent literature in terms of proposed mechanism, study design, results, and study limitations.

Population Databases and Data Warehouses (e.g., SEER Database)

The SEER database collects cancer data including incidence, prevalence, and survival and represents 26% of the US population. The SEER database is an example of a clinical data warehouse based on collections of data from defined populations. It comprises 17 population-based cancer registries from the Alaskan Native Tumor Registry, Arizona Indians, greater California, Connecticut, Detroit, Atlanta, greater and rural Georgia, Hawaii, Iowa, Kentucky, Los Angeles, Louisiana, New Jersey, New Mexico, San Francisco–Oakland, San Jose–Monterey, Seattle–Puget Sound, and Utah. SEER also contains data on cancer mortality for the entire United States. This database is primarily employed for comparative cancer statistics based on age, geographic region, socioeconomic class, and race. Among the many possible comparisons, this broad data set also allows analyses related to health disparities. The SEER system includes both a database of cancer registry patients and software to perform statistical analyses. Population databases such as the SEER database provide access to high-quality clinical data and a relatively easy interface to perform studies for retrospective association.

Institutional Database Studies (e.g., Veterans Administration)

The VA employs EHRs of all veterans who undergo medical evaluation and treatment at their facilities. Not only does this wealth of clinical data provide the ability to perform powerful retrospective studies, the VA also enrolls veterans into prospective studies including random controlled trials. IRB approval is required to perform human research utilizing VA materials.

The VA has completely transitioned to the use of EHRs ahead of national mandate. This created a very comprehensive database in terms of clinical details; however, the issue here is that most of the data are textual (8). Coding variables that include ICD-9 and CPT codes are available but have not been universally applied given the VA's status as a single-payer system. Furthermore, the software systems available for searching and extracting patient data from VistA are limited with respect to data mining and clinical studies.

BASIC SCIENCE ADJUNCTS TO TRANSLATIONAL MEDICINE

The complete sequencing of the human genome in 2001 opened the door to a new world of analyses (20,21). Knowledge of genomic, proteomic, and related resources is often essential in transitioning clinical data into translational data. Here we present just a few of the possible resources that assist in bridging basic science and clinical data. Most of these resources are available to the public and represent open-source data.

ENSEMBL is a database comprising multiple vertebrate and eukaryotic genomes that is freely available (www.ensembl.org). Multiple search methods and types of analysis are possible. Searches can also be based on disease names or physiologic functions. Therefore, one may quickly search for genes involved in disease or other processes.

The NCBI provides a multitude of searchable resources including PubMed (see Clinical Database Applications), OMIM, SNP, and others. A review of their functions and tutorials can be readily obtained by going directly to the NCBI home page (www.ncbi.nlm.nih.gov).

The Research Portfolio Online Reporting Tool (RePORT) provides information on all funded research grants from the NIH including areas of research, funded organizations, success rates, and budgets. In addition, the RePORT Expenditures and Results (RePORTER) supports queries of all current and historical funded grants. Most importantly, this allows for searches of funded grants by terms related to the research topic. Therefore, a researcher can identify funded studies in the RePORTER database in order to prevent redundancy in their research grant application (www.report.nih.gov/).

Bioinformatics supports the analysis of a multitude of areas in basic science research. In genomics, gene identification and genome assembly may be predicted. Protein structure predictions and protein interactions may also be predicted. These can lead to rational drug design and discovery. If a potential candidate protein or genetic sequence is isolated as a target molecule during pathogenesis, these resources may assist in identifying additional mechanisms or pathways, providing new directions in translational research and interceptive therapeutics.

Translational Research Databases

As advances in molecular biology and refinements in techniques such as gene therapy develop, translational research databases are steadily emerging. However, they are perhaps the most difficult kind of database to populate and analyze. Currently there are a small number of standard genetic tests reported in EHRs. In the future, genetic screening tests, such as a disease-specific cDNA microarray test, may become readily available and incorporated into EHRs. Textual data are common in genomics, proteomics, PubMed literature, and EHRs (22). Multiple text associations are possible per entity, such as abbreviations, syntax, semantics, and specific sequences. Effective search methods utilizing text-based data sets require either exhaustive manual effort if the database is limited or search engines for larger databases.

Obtaining sufficient power in databases requires larger populations. To effectively populate translational databases, collaboration between collection centers is necessary. Collaborative efforts may include private hospital systems, state and federal systems, and academic hospitals. Data themselves may present a problem, particularly in collaborative databases. If data are to be compared across multiple sources, then standardized coding must be presented such that data are presented in an equivalent manner. This may require manual coding and incorporation of translational data into translational databases.

Private and public databases of genetic information from human tissue samples are another source of translational databases (Reviewed in 26). These either record a limited set of clinical data along with the genetic information or link to the genetic information such that associated clinical data may be acquired from EHR.

Ethical Issues in Translational Research

Translational databases create ethical challenges due to the inclusion of genetic and other personal data. Discrimination based on genetic data may occur at a variety of levels or influence insurance coverage. In response to this evolving concern, Congress passed the Genetic Information Nondiscriminating Act (GINA) in 2008 (23). Title I of GINA seeks protection for alteration of health insurance coverage based on genetic information. Title II provides individuals with protection related to genetic information from employer and workplace discrimination. GINA also amends genetic information to be part of the clinical information protected under HIPAA. Some researchers have fought against the stringent restrictions in GINA, believing that they will create a bureaucracy of increased costs and compliance to perform studies involving genetic information. This has been deemed akin to the effect of HIPAA on human research. Finally, genetic information about a patient opens doors to similar information about related family members, against whom similar discrimination may ensue. These issues have undergone philosophical debate for many years and will create a greater impact as advances in genetic testing further develop.

Translational Database Studies

Small-scale translational databases can be readily formed from patient cohorts at a single institution. Such collections may be prospective, randomized, and controlled. Given the generally limited numbers of patients, textual clinical data coding and the security overseen by an IRB may be managed by a few researchers. Although powerful in answering a limited number of questions related to specific accrual criteria, small translational studies cannot compare to the statistical power of a large-scale database.

The electronic MEdical Records and GEnomics (eMERGE) network is a consortium of five institutions collaborating to merge DNA repositories and EHRs (24,25). Currently, genome-wide association studies to provide genotyping have been performed for a small number of specific primary disease phenotypes. Each of the five sites has created a biobank combining genomic data and EHR-based clinical correlative data. Challenges in synthesis of data between the sites have been addressed. Unfortunately, the cohorts may not be comparable for some conditions. However, the eMERGE system provides a valuable example for the feasibility of collaborative translational research.

As part of EHRs, comprehensive medication histories are recorded, which may provide important translational associations. Both clinical utility and technical difficulties in synthesizing these data into multi-institutional data warehouses, also referred to as biobanks, have been reviewed (26). Collaborative efforts of Johnson and Johnson, the Cancer Institute of New Jersey, and St. Jude Children's Research Hospital has created a translational database combining biomarker data (e.g., gene expression profiles, genotypes, serum protein panels, and others) with clinical correlations from internal clinical trials (27). Open-source tools were used to analyze the data. This database has been mined for multiple drug discovery functions including indication selection and trial design. The related intuitive graphical interface allows for quick validation of hypotheses such that the effect of small changes may be evaluated. One problem with such systems is the propensity to create analysis and interpretation biases by tailoring search parameters to find significant effects.

Crowley et al. (28) furthered a research-based translational database of deidentified clinical and tissue specimen data by integration with the Cancer Biomedical Informatics Grid (caBIG). This created standardized architectural grouping and vocabulary with graphical interfaces and text-based search mechanisms. Although the caBIG database was successfully generated, no multi-institutional collaborative data mining studies have yet been produced. This also exemplifies the multidisciplinary and costly nature of creating a multi-institutional translational data warehouse.

Currently, translational databases represent a promising and novel technology that is under continuous development. Given that the establishment of translational data warehouses requires significant financial commitments, for smaller groups we recommend seeking opportunities to be included in existing and emerging institutional and multi-institutional studies.

CONCLUSION

Clinical information from patient records and medical research has been stored in paper-based form for centuries. Over time, this paper-based system has consumed increasing space, created inefficiencies in storage and acquisitions, and most notably, delayed access to medical care. In contrast, the ability to store clinical information digitally into a computer

database allows for instant and more efficient access to patient records and research data, and has revolutionized all aspects of medical care and research. To this end, the field of medical informatics is an emerging discipline that relates computer applications and algorithms in the delivery of medical care to ultimately improve human health.

HIGHLIGHTS

- In 2009, US Congress enacted into law the HITECH Act, which implemented new policies to induce adoption and "meaningful use" of EHRs by hospitals and physicians. Therefore, the American Academy of Otolaryngology—Head and Neck Surgery Medical Informatics Committee recently published formal recommendations and guidelines to encourage the adoption of EHRs.
- Most EHR databases currently available are stored as narrative text and other textual data, presenting research challenges for data mining and other clinical research.
- There are many clinical databases available for the researcher; examples include PubMed, SEER database for cancer population studies, VA EHR, or VistA.
- The complete sequencing of the human genome in 2001 is uncovering the molecular basis of human pathologies. Basic Science database includes ENSEMBL, which is a database comprising multiple vertebrate and eukaryotic genomes and the NCBI.
- Translational Research databases are emerging; however, they are the most difficult kind of database to populate and analyze due to limits in technology and small population size.

Telemedicine for Otolaryngology

205

John Kokesh *Chris Patricoski* *A. Stewart Ferguson*

Telemedicine utilizes technology to enhance communication and provide services over a distance. In this way, "telemedicine" represents an evolution in health care that has adopted the technologies and communication infrastructure now available in society. The telephone and fax machine were the earliest telecommunication tools used in clinical practice, and are now so ubiquitous that we can hardly imagine medicine without them.

With the rapid advances in technology and telecommunications, and perhaps more importantly, widespread societal acceptance of technology, a new generation will redefine how medicine is practiced in the future. "Telemedicine" will likely become an antiquated term requiring redefinition, no longer describing a niche area in certain medical specialties but rather a methodology by which modern information transfer is used to improve the practice of medicine.

This chapter examines the current telemedicine technologies and present applications of telemedicine in otolaryngology. While telemedicine has grown significantly in the last 10 years, there is a need for further adoption throughout the United States. The realization that improvements are needed in access for care, costs of care delivery, and availability of medical specialists will likely help remove some of the barriers that have thus far thwarted widespread innovation and adoption of telemedicine in otolaryngology. The nature of the specialty, with well-developed and extensive use of endoscopy, microscopy, photographic imaging, and physiologic data, makes otolaryngology a potential beneficiary of an expanded role for telemedicine in the future practice of medicine.

DEFINITIONS

The American Telemedicine Association (ATA) defines telemedicine as "the use of medical information exchanged from one site to another via electronic communications to improve patients' health status" (1). Telemedicine has been traditionally divided into three areas: Interactive Video Teleconferencing (VTC), Asynchronous Store-and-Forward (S&F), and Remote Patient Monitoring (RPM). While the distinction between these categories has begun to blur with advances in device technology and means of information transfer, it is worthwhile to review each as well their current usage in medicine.

The term "VTC" telemedicine applies to a medical encounter performed over a live teleconference link with video and audio and, in some instances, a live display of data from remote medical devices. As commonly practiced, a "presenting provider" is physically present with the patient to assist with the interview, conduct aspects of the examination, and operate devices to obtain parts of the examination to be transmitted. The presenting provider, for example, may operate an endoscope to provide live video of the examined body system. The "consulting provider" is located at a distance and receives the live video feed. There is synchronous communication between the providers and the patient; questions can be asked and immediately answered. The consulting provider may direct certain parts of the examination. The encounter may be recorded for future reference. Some of the advantages of VTC are that it is interactive, patient movement and affect can be assessed, and a "human" connection between the involved parties can be established. The consulting provider has the ability to conduct an interview similar to an in-person exam and can help direct the encounter. The disadvantages of VTC are that all involved parties must be available simultaneously for the encounter, technical and network support is needed to ensure full function at the time of the scheduled encounter, and sufficient bandwidth is required for adequate video quality. VTC has generally been most successful when used as part of an integrated health system where coordinated scheduling, technical support, training, and funding are provided (2). Examples of medical specialties

where VTC has been successfully used include psychiatry and mental health services, cardiology, and intensive care unit consultation (Tele–ICU) (3,4). VTC has also been used in the recent development of "telestroke" networks, where a remotely located neurologist assesses patients with evolving strokes and decides whether thrombolytic therapy should be administered (5).

"S&F" telemedicine involves the capture, storage, and transmission of data between providers for the purpose of obtaining medical advice and opinion. As commonly practiced, the "creator" is physically present when interviewing the patient, conducting an examination, capturing data, and documenting the encounter in a telemedicine case. The "consultant" at a remote location would then review the transmitted data after it was sent in its entirety. S&F is asynchronous; the providers need not be available at the same time, and the created "case" may be viewed minutes, hours, or days after it was created and transmitted. Typical data that are captured and utilized in S&F include clinical histories, vital signs, digital photos, radiology images, endoscopic images, scanned documents, audiograms, tympanograms, and heart and lung sounds. The advantages of S&F are that it does not require simultaneous availability of providers, thereby avoiding scheduling and logistic problems. It can be extremely time efficient for the consultant as complete data collection and organization of information have occurred during creation of the case, often along predetermined guidelines (Fig. 205.1). S&F can be used with low or interrupted bandwidth, enabling its use in very remote or infrastructure-deprived locations. Finally, once set up with the appropriate software, security, and operational standards, S&F "works like e-mail" requiring much less ongoing maintenance and support than VTC. Disadvantages of S&F are that real-time interaction between providers is not possible; the consulting provider cannot direct the exam (though they can asynchronously request additional information), and sustained movement, voice, and affect of the patient cannot be assessed (though short video files are now easily transferrable). S&F has long been successfully used in those specialties where the assessment or "read" of the consultant regarding static clinical data is the valued service. Well-established examples are teleradiology (6), teledermatology (7), and telepathology (8).

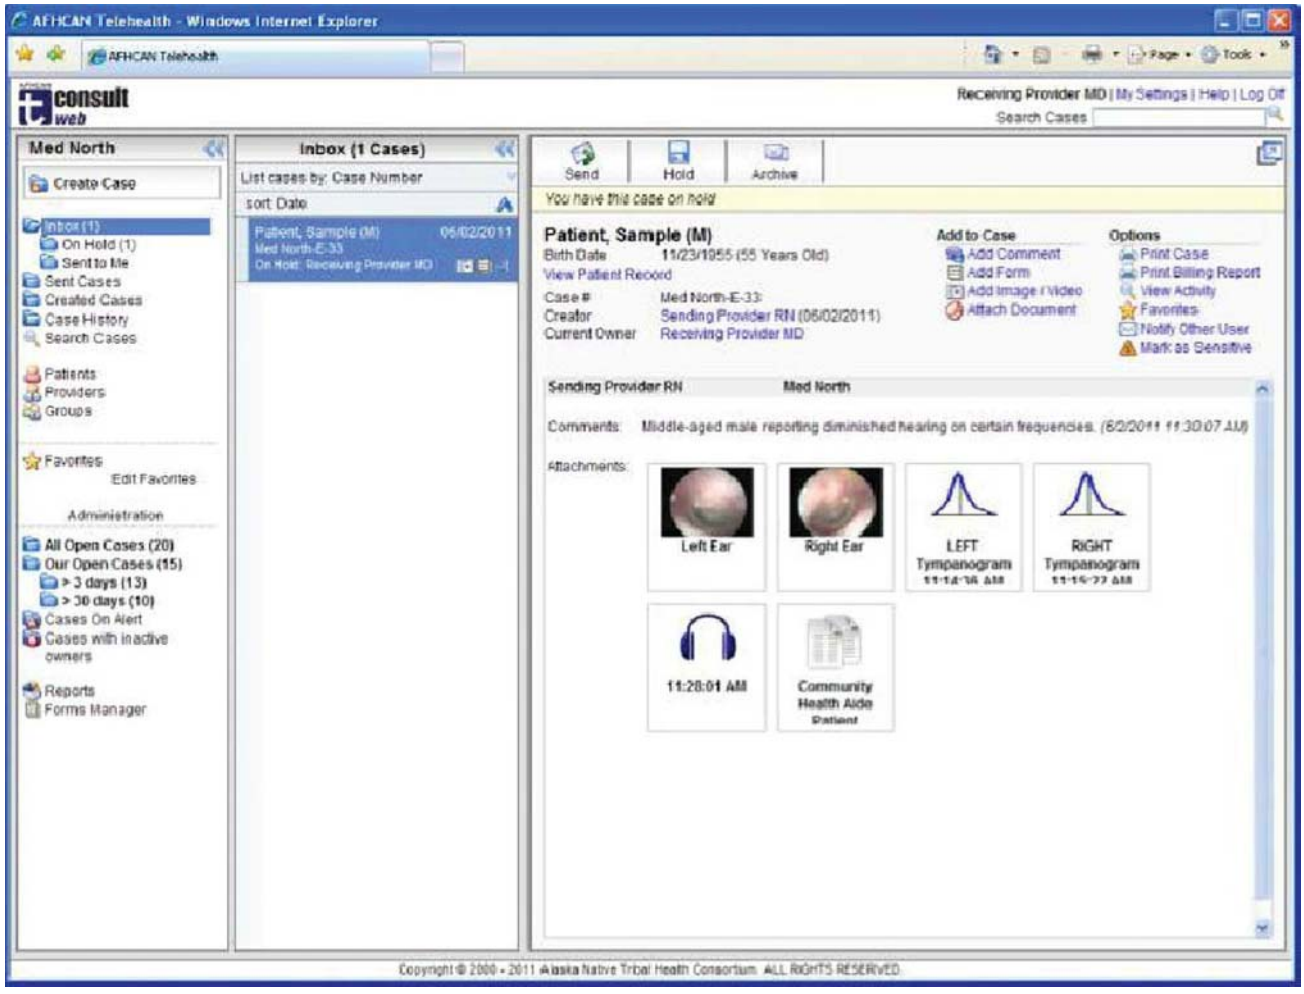

Figure 205.1 Alaska Federal Health Care Access Network (AFHCAN) tConsult software. Clinical information and data have been organized for review by the consultant.

RMP technology enables the monitoring of patient health data originated from the patient's home, nursing facility, place of employment, school, and other locations. It is most often employed in the patient's home and, as such, is often called "home telehealth." RPM almost always involves capture of data similar to S&F and sometimes includes video. To date, RPM has proven useful for the management of chronic disease states such as diabetes, congestive heart failure, and chronic pulmonary disease (9,10). Used appropriately, RPM facilitates access to care, patient and family involvement and education, and early identification and intervention for acute illness or health status decompensations. RPM holds tremendous promise for cost savings through improved chronic disease management, especially for integrated health systems (11). From a commercial standpoint, RPM represents a large potential market, and device manufacturers are rapidly adding new products to the field. For these reasons, this is the most rapidly growing field in telemedicine, and clinicians will likely have increasing opportunities to use home monitoring in the future.

A final category of telemedicine deserving mention relates to the use of telemedicine technologies in the performance of surgical procedures. In telementoring and teleproctoring, a distantly located "expert" surgeon monitors and assists a surgeon at a distant location performing a surgery. A typical current application would involve using a live VTC link used to mentor an endoscopic procedure (12). Telesurgery, the performance of a surgical procedure by a remotely located surgeon using robotic devices, is currently the subject of feasibility studies and demonstration projects (13).

SECURITY AND HIPAA

Telemedicine is no different from other forms of clinical care in regard to the applicability of regulations governing privacy and security. The use and disclosure of an individuals' health information (protected health information [PHI]) by providers and organizations are subject to national standards and regulations—regardless of the care delivery model. Most notable among these are the so-called HIPAA Privacy and Security Rules and the more recent HITECH Act:

- The Standards for Privacy of Individually Identifiable Health Information (Privacy Rule) was issued by the US Department of Health and Human Services in 2000 to implement the requirements of the Health Insurance Portability and Accountability Act of 1996 (HIPAA). The Privacy Rule standards address the use and disclosure of individuals' health information called "protected health information" by organizations subject to the Privacy Rule (covered entities) as well as standards for individuals' privacy rights to understand and control how their health information is used.
- HIPAA also mandated the creation of national standards for the security of electronic health care information, which were then released in the final "HIPAA Security Rule" in 2003. This final rule specified a range of administrative, technical, and physical security procedures for covered entities to use to for electronic protected health information (ePHI); the standards were delineated into either required or addressable (optional) implementation specifications.
- More recently, the Health Information Technology for Economic and Clinical Health Act (HITECH Act) was passed as part of the American Recovery and Reinvestment Act of 2009 (ARRA). Because HITECH contains incentives designed to accelerate the adoption of electronic health record (EHR) systems and potentially generate a massive growth in the exchange of ePHI, the HITECH Act further broadened the scope of privacy and security protections established under HIPAA.

A good "rule of thumb" is to recognize that a telehealth system should be treated no different than an EHR system in regard to privacy and security. Telehealth systems are designed to capture, transmit, store, and display ePHI—as are EHR systems. Many telehealth systems interface to EHRs and share information in a back-and-forth manner to provide a more complete view of the patient record. Telehealth systems sometimes contain information that is potentially "more identifiable" of the patient as they may contain images of the patients face or other body parts.

It is not possible to provide a thorough review of the HIPAA and HITECH regulations as they apply to telehealth systems, but the following features are recommended in any telehealth system to maximize the ability to comply with HIPPA and HITECH. While the general concepts apply to VTC, S&F, and RPM, the remainder of this section uses S&F telehealth as an example for how these standards and regulations may apply.

- All data should be encrypted "at rest" and during "transport." Data flow (i.e., "transport") in a telehealth system from a computer (or system) in the patient exam room to other systems where remote providers (or specialists) can view the data. Data may stay on a server (at rest) or a desktop PC for hours or days until a provider can view that data. Data that are encrypted are not "readable" or "viewable" without the right key to "decrypt" the data. This prevents unauthorized users from accessing the data and provides a significant level of privacy and security protection. While some organizations elect to not encrypt data flowing within their private network, telehealth services are becoming much more common between organizations with data flowing outside of organizational networks and potentially across Internet links, further accentuating the need to encrypt the data.
- Access to data through a browser—such as Internet Explorer or Safari—should rely on an encrypted connection (e.g., "https" instead of "http"). When this access

occurs across the Internet or outside of an organization's trusted network, the Web site should provide "https" connectivity using a security certificate from a trusted organization—thereby allowing users to have greater trust in the web server's authenticity.

- Systems that require data to move between organizations or across nonsecure networks should include a mechanism to make sure the data do not change (data validation) and a mechanism to verify the site or provider that originated the data (nonrepudiation). This is usually accomplished through electronic signatures and "hash" algorithms.
- The telehealth system should integrate with the user authentication mechanism used by the organization, so the user account can be managed through a central mechanism and password policies can be enforced (e.g., regular changes, minimum password length, and complexity).
- All major user activities should be tracked within the telehealth system through an audit mechanism. As a minimum, all successful and unsuccessful log-in attempts should be logged as well as any changes that impact patient data.
- Users should have sufficient access for their needs, but no more. Role-based security is an excellent mechanism whereby users are assigned to various roles (e.g., consultant, trainer, clinical administrator) that define their access to telehealth data and functionality. Time-outs should be employed to limit access to data should a provider leave a workstation prior to logging out.
- Recognizing that not all telehealth cases are necessarily equal, the telehealth system should provide a mechanism to indicate when a case is "sensitive" or requires tighter security than other cases. Such cases might include abuse cases, mental health cases, or HIV/AIDS cases.
- Similar to EHR systems, telehealth equipment (workstations, servers, medical devices) can all contain ePHI and as such need to be physically secured to prevent loss of data due to theft or unauthorized access.
- The telehealth system needs to be managed and protected similar to an EHR system. This would include, for example, accepting updates only when tested and provided by a reputable source, backing up data and providing for disaster recovery efforts, active defenses against viruses and other malware, and protecting equipment against loss of power or intermittent power surges.

It is not uncommon to find providers that rely on e-mail as a simple telehealth solution—allowing for the exchange of images and basic textual information about a patient. This should raise significant concern based on the proceeding information, as an e-mail system is often not considered a secure system by most organizations and will limit or impede and organization's ability to achieve HIPAA compliance.

USES OF TELEMEDICINE IN OTOLARYNGOLOGY

Telemedicine has been used in the field of otolaryngology since the early 1990s. Use has occurred primarily in those situations where there was a remote, isolated population to serve; a shortage or lack of availability of otolaryngologist; or, more recently, backlogs of patients needing otolaryngology care inadequately addressed by the existing delivery system. Applications have been partially driven by available technologies and their cost, and the spectrum of clinical services that can be delivered at a distance has increased with advances in technology and communication infrastructure. Finally, most of the usage and research in the use of telemedicine in otolaryngology has occurred in those settings where the financial and regulatory barriers that have limited the widespread use of telemedicine in the United States are less formidable and where telemedicine programs have been designed to meet a specific clinical or population need. Examples include programs run through the United States Department of Defense and the United States Public Health Service as well as programs in countries with national health plans.

Otology and Neurotology

The ability to obtain and transmit diagnostic quality images of the tympanic membrane and middle ear has been well established. Pedersen, in pioneering work done in Norway, showed that a video otoscope coupled to a VTC network could be used to allow a remotely located otolaryngologist to direct patient examinations and establish diagnoses and treatment plans. This resulted in improved access for otolaryngology care as well as reduced cost for care delivery to isolated populations (14). Additional work using this methodology has verified that high-quality images can be routinely obtained with the video endoscope, even in pediatric populations (15). Still images of tympanic membrane obtained by a video otoscope and accompanied by audiologic and tympanometric data and transmitted using S&F technology were used to deliver otology consultations to patients in remote areas of Western Australia (16). Exam findings and diagnoses based on S&F examination using digital images from a video otoscope for children with previously placed tympanostomy tubes were found to correlate highly with those established by in-person encounters with otolaryngologists using binocular operating microscopes (17). S&F telemedicine using tympanic membrane images, clinical histories, and audiologic data has been shown to allow for accurate planning for chronic ear surgery (18).

This work has demonstrated that telemedicine, whether VTC or S&F, is a useful tool for delivering otology care. As diagnosis depends to a great degree on the physical characteristics of the tympanic membrane, image quality is critically important. Images must be in focus, adequately

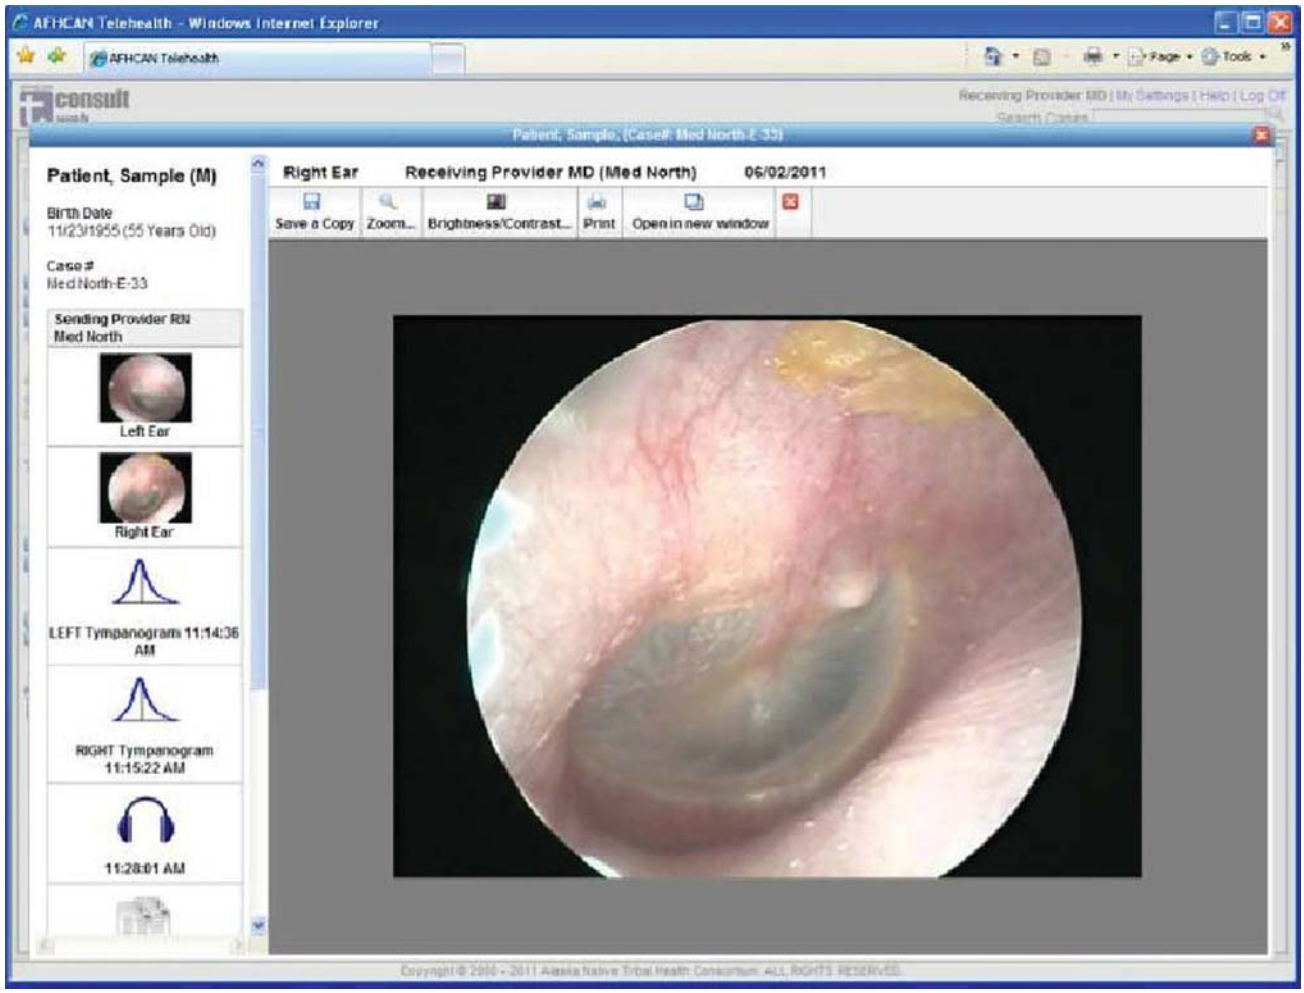

Figure 205.2 Typical otology case in AFHCAN tConsult software. Case includes images, audiogram, tympanogram, and clinical history.

illuminated, and free of obstruction. A high-performing video otoscope proves to be a worthwhile investment, and training must be provided to those acquiring the images to ensure consistent high quality. While most video otoscopes do allow for insufflation, and tympanic membrane mobility can be assessed if VTC is used, the addition of tympanometric data has generally found to be a useful adjunct to images. When "packaged" with digitized clinical histories and audiograms, an otology "case" can be created that can be reviewed by the otolaryngologist and in most cases lead to an accurate diagnosis and treatment plan (Fig. 205.2). When used over an S&F platform and coupled with clinical guidelines and standards for the information required by the consultant, telemedicine can become an extraordinarily efficient way to diagnosis, triage, and offer treatment advice for otologic disease.

Recent experiences have demonstrated the utility of telemedicine in delivering otologic and neurotologic care. S&F telemedicine has been used in rural Alaska to deliver otology care with dramatic effects on access and reduced waiting times. Alaska Natives have a high burden of middle ear disease, and many are remotely located with difficult access to specialty care (19). To address these issues, a statewide telemedicine system, the Alaska Federal Health Care Access Network (AFHCAN), was created (20). To manage otologic disease, primary care physicians and midlevel providers have been trained in the use of otoscopes, tympanometers, and screening audiometers and use S&F telemedicine to obtain consultation from otolaryngologists at an urban referral center (21). Populations receiving this care model realized markedly reduced waiting times for care and overall improved access to the opinion of an otolaryngologist (Fig. 205.3) (22). Audiologists trained in video otoscope image acquisition and the use of S&F telemedicine have partnered with consulting otolaryngologists to deliver care to extremely remote populations in Alaska, making use of mobile devices and equipment (Fig. 205.4). Effective triage, cost savings from avoided travel, and identification of undiagnosed, serious disease states were demonstrated (23). In post hurricane Katrina in southeast Louisiana, clinical protocols were combined with a blend of S&F and VTC telemedicine to allow a distantly located consulting neurootologist to assist local providers in providing neurotologic care. With appropriate planning, this model was

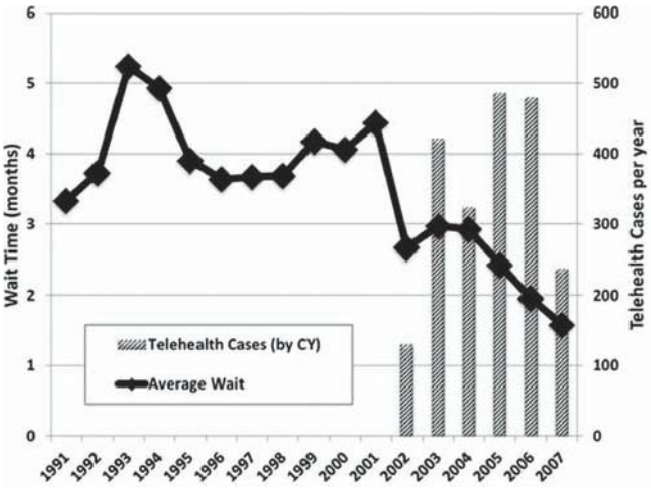

Figure 205.3 Average wait times for otolaryngology appointments. Nome, Alaska, 1991 to 2007. Wait times for in-person clinic appointments steadily decrease as telemedicine usage increases.

found to be very effective for service delivery in this area of need (24).

An effective and gratifying use of S&F telemedicine in rural Alaska has been for the identification and treatment of sensorineural hearing loss. Working closely with audiologists, protocols have been developed to allow for an audiologist to obtain medical clearance for hearing aid fitting without requiring an in-person encounter with the otolaryngologist. This has resulted in savings of travel costs and inconvenience for the patient and has meant for many patients access to a hearing aid that they would not have otherwise had. This model has also greatly strengthened the working relationship between audiologist and otolaryngologist. In the future, S&F telemedicine may assist otolaryngologists and audiologists in maintaining a collaborative approach to the management of patients with hearing impairment, an area of some recent controversy (25).

In summary, telemedicine is an effective *tool* that can be used to *assist* the otolaryngologist in delivering care for otologic disease. Pathologies can be diagnosed, advice can be given to primary care providers, and patients can be triaged to their most appropriate level for care—all by the specialist with the most expertise in the disease process. However, as with all telemedicine, there must be a means to deliver traditional, in-person medical or surgical care for those identified to need such.

Pediatric Otolaryngology

Isolated pediatric populations with limited access to the care of an otolaryngologist have been the subject of studies evaluating telemedicine as a care delivery model. VTC was used to evaluate children with problems such as sleep disorder breathing, otitis media, and sinusitis. Otoscopes were used for ear imaging, and a modified, diffuse light source coupled to an otoscope was used to image the oral cavity and pharynx. Diagnoses and treatment plans given by remotely located otolaryngologist were found to correlate highly with those made during a traditional in-person encounter with an otolaryngologist (26). This same methodology was used to do a cost minimization analysis for a telepediatric otolaryngology screening program in Western Australia. By avoiding travel costs for patients and their families, telemedicine-based services were found to be less

Figure 205.4 Mobile audiology and telemedicine equipment transported to a highly remote Arctic area. Specialty care is provided by a midlevel provider telecommuting store-and-forward cases to specialist in an urban center.

expensive than those delivered through a traditional outpatient clinic, once adequate telemedicine volume was achieved (27). A similar screening service directed at ear disease using a medical van with wireless connectivity served children in remote Australia, with high satisfaction levels for those patients served (28). Telemedicine appears to offer one solution for delivering basic otolaryngology diagnostic services to otherwise underserved pediatric populations.

Head and Neck Oncology

An interesting use of VTC has been for extending the availability of multidisciplinary teams (MDTs) for the diagnosis and management of patients with head and neck cancer. MDTs are used to establish diagnosis, staging, and treatment plans. In addition, they ideally involve specialties such as nutrition and speech pathology to develop comprehensive plans tailored to the patients needs. It can be a challenge to bring together all the participants for MDTs, and there are costs associated with travel and time away from work. Also, MDTs function best when all the necessary information has been prepared and distributed prior to the meeting. VTC has been used to address these issues allowing providers and, at times, patients to participate remotely and share information. Provider satisfaction and cost savings have been demonstrated (29,30).

As MDTs function best when they manage a large number of cases per year, they tend to be offered primarily in major centers. VTCs have allowed for both patients and their local providers from remote areas to fully participate and benefit from fully resourced, more centrally located MDTs (31). In this way, telemedicine again allows for widespread access to concentrated medical expertise.

Home monitoring may become a more important adjunct in the care of head and neck cancer patients as devices and services become more widely available. Pain control, nutrition, and respiratory status can all be monitored remotely, allowing for earlier management at home in the perioperative period. Patients with chronic needs could benefit from regular virtual nursing "visits" addressing concerns and identifying and intervening on problems early. Patient education and family involvement can also be promoted using videoconferencing made available through home devices.

Excellent images of the nasopharynx, nasal cavity, oral cavity, pharynx, and larynx can be obtained and transmitted using standard rigid endoscopes and cameras. Formal studies examining the diagnostic accuracy of transmitted images for head and neck tumors have not been done.

Laryngology and Speech Disorders

With advances in endoscopes and imaging technology, it has become a relatively routine matter to visualize and image the larynx. Most family practitioners and emergency room physicians are trained in the use of flexible scopes, though recognition of pathology is often a difficult task for the occasional examiner of the larynx. A means by which to easily obtain the opinion of an otolaryngologist would be useful. There has been some work showing that asynchronous examination of either still laryngeal images or short video clips correlates well with in-person examination (32,33). Flexible laryngoscope images transmitted by VTC to a consulting otolaryngologist have been used to establish diagnosis and treatment plans for US military personnel (34). It is now possible to capture and transmit short video clips of a dynamic laryngeal exam using an S&F platform, which creates interesting possibilities for asynchronous expert consultation. Technologic advances, such as high-resolution distal chip camera endoscopes that allow for improved digital images of the larynx, may lead to more interest in developing telemedicine applications for laryngology.

For speech disorders, telemedicine applications are being investigated for both diagnosis and treatment. Early work indicates that it may be feasible to identify some voice disorders by analyzing remotely transmitted voice, using either standard telephone networks or voice over the Internet (35,36). Automated systems could be set up to facilitate screening for new diagnoses or monitoring of existing voice disorders. VTC has been used to deliver speech pathology services to remote patient populations. In small studies, efficacy has been shown to be comparable to standard in-person speech therapy, and patient acceptance has been good (37). Given that speech pathology can be very difficult to make available to isolated or underserved populations, telemedicine holds great promise to address this problem (38).

Facial Plastics and Trauma

Images have long been used in facial plastics for the purposes of documentation, planning, and follow-up, though a role for remote diagnosis and consultation is still being developed. Telemedicine has established utility in the field of dermatology, and high-quality images transmitted to a consultant dermatologist have been shown to have comparable diagnostic accuracy to an in-person evaluation for conditions such as skin malignancy (39). In remote Alaska, transmittal of store-and-forward images to consultants at a regional trauma center has been used to remotely give advice on wound closure for traumatic soft tissue facial injuries. For more severe injuries and for patients with facial fractures, a combination of photographic and radiologic images "packaged" with clinical histories is used to make triage decisions and to assist in preoperative planning (40). With the widespread availability of "smartphones," patients can take and send their own images for review. Interesting early work is being done with this model, and patient-generated telemedicine may play an increasing role in the future, especially in the area of facial plastics (41).

Telemedicine in the Operating Room

Telemedicine can be used to bring remotely located expertise into the operating room, allowing a more experienced or specialized surgeon to advise and mentor another surgeon both before and during an operation. Telementoring may involve the use of image review and even computer simulation prior to an operation to plan a procedure and receive input from a remotely located surgeon (42). During an operation, VTC can be employed so that the remotely located surgeon may counsel the surgeon performing the operation. This method of remote consultation has successful applications for endoscopic sinus surgery where the video from the endoscope is fed simultaneously to both surgeons (43) and a VTC connection has been used to supply intraoperative consultations for other complicated procedures to surgeons in remote Pacific islands (44). Remote monitoring and intraoperative testing for cochlear implantation surgery have been shown to be cost-effective and to maximize the availability of audiologists skilled in this area (45). The advent of robotic surgery presents the possibility that telesurgery, where a remotely located surgeon controls the robotic device, may someday become clinically applicable.

BARRIERS TO ADOPTION

Cost of technology, immature telecommunications infrastructure, and lack of evidence of clinical utility were often reasons that initial interest in telemedicine did not progress to actual clinical use. In the past, the barriers to entry were simply too high for most physicians, practices, and health care systems. For example, the costs of a dedicated VTC system were close to being prohibitive. Many of these previous problems have been resolved. The situation is different today with other challenges that need to be addressed.

One key barrier to adoption of telemedicine is the learning curve and hesitation associated with a new technology and confidence that the technology is a solution to the user's problem (46–48). The adoption of technology by the typical American consumer is making this less of an issue, as comfort using software, smartphones, and tablet PCs has disseminated into the workplace.

There are additional economic, organizational, and behavioral knowledge barriers that inhibit the diffusion of telemedicine (49). Further barriers to setting up a telemedicine program are related to organizational communication and structure (50).

The most perplexing issues facing telemedicine are more sociopolitical. They have been identified during the early growth of telemedicine and include (a) interstate licensing and institutional credentialing of physicians, (b) legal liability and litigation, (c) individual client or patient autonomy and right to privacy, (d) reimbursement, (e) knowledge about telemedicine, and (f) system design and infrastructure (51).

Licensure and Credentialing

A telemedicine encounter by its nature may create a licensure and credentialing quandary; the patient may reside in a different state where the consulting physician may not hold a license and may be receiving care at a facility at which the consulting provider may not be credentialed. In general, the consulting provider must have a license to practice medicine in the state from which the patient is presented. The state-based licensure model makes it more difficult to easily expand telemedicine across state lines. Some states have addressed this issue with consultation exceptions, reciprocity agreements, or special telemedicine licenses. There is some interest in a joint state–federal approach to designate a national telemedicine license (52). More likely, the state model will be retained, but efficiencies in multi-licensure will grow with entities such as the federal credentialing verification service. The federal health care system requires physicians to have only one state medical license. The Veteran's Administration, Department of Defense, and Indian Health Service have been able to take advantage of this to grow cross-state telemedicine.

The consulting provider also needs to be credentialed at the originating facility. Again, advocacy groups are proposing less onerous "credentialing by proxy" rules that would allow facilities to enter agreements whereby for the purposes of providing telemedicine, the consulting provider need only apply and obtain full credentials at one facility. At the time of this writing, clarification on credentialing for telemedicine is forthcoming from CMS (Center for Medicaid and Medicare Services.)

Professional Liability

Providers interested in offering care through telemedicine would be best advised to discuss their coverage with their carrier. The authors are unaware of instances where coverage was denied specifically for medical care within the provider's scope of practice delivered through telemedicine.

The experience delivering neurotology care by means of telemedicine to patients in post-Katrina New Orleans gives an excellent recounting of how the barriers described above were addressed to allow for this program to carry forward, giving a sense of what difficulties the current environment presents (24).

Reimbursement

Past Medicare rules allowed reimbursement only for VTC in rural areas. A professional fee was paid to the consulting provider, and a small facility fee was paid to the origination site. Reimbursement for VTC was extremely low considering the technology and network costs and the time commitment required of the providers for a typical VTC session. This made VTC impractical in the fee for service environment. This situation essentially persists today, and a strong economic case

for VTC can be made only in a systems context where savings such as avoided patient travel costs offset the costs of VTC and provider time commitment. Adoption of VTC for the provision of otolaryngology services outside of systems such as the US military will require a different economic model. The cost of VTC has dropped significantly with the advent of excellent, low-cost web cameras and the ability to do VTC over the Internet rather than on more expensive dedicated point to point networks. This coupled with changes in the reimbursement model could lead to a wider array of economically feasible clinical applications.

The reimbursement environment for S&F telemedicine is variable by state and payer and therefore complex and confusing. At least 21 states currently offer Medicaid reimbursement for telemedicine services, some of which include S&F: Alaska, Arkansas, California, Georgia, Hawaii, Illinois, Iowa, Kansas, Kentucky, Louisiana, Minnesota, Montana, Nebraska, North Carolina, North Dakota, Oklahoma, South Dakota, Texas, Utah, Virginia, and West Virginia, and each state has its own guidelines for dealing with reimbursement (53,54).

Reimbursement for two forms of S&F telemedicine—teleradiology and telepathology—has long been allowed, and successful business plans for both exist. In Alaska, Medicaid began to offer reimbursement for telehealth for both "store-and-forward" and live videoconferencing in 2002. Alaska Medicaid established a practice of reimbursing S&F encounters using the evaluation and management coding system, stipulating that a GQ modifier be used to designate S&F telemedicine. Private insurers eventually adopted this practice, and now most in Alaska reimburse for S&F telemedicine at rates equivalent to a face-to-face encounter coded at a similar level.

In both Arizona and New Mexico, a flat fee structure has been designed for this purpose. The ATA has been active in lobbying for a comprehensive national policy for S&F telemedicine reimbursement. Until that is achieved, providers should check with payers in their state for their current policy. Until there is more clarity and predictability about reimbursement for S&F otolaryngology, it will be difficult to develop the business case for it in the fee for service environment.

Program Building and the Problem of Scale

The benefits of telemedicine are best seen in the context of a program or a health care system, where a coordinated network of providers delivers care using telemedicine to a population of patients, matching clinical need with the capacity to meet that need. A successful telemedicine program depends on a well thought-out and executed plan that addresses the many aspects that underlie a telemedicine effort. Technology must be assessed and selected to best suit clinical needs, and it must be assessed on an ongoing basis, as devices in particular evolve rapidly. Workflows need to be planned to deliver consistent service and to ensure that telemedicine is never a "step-down" from traditional face-to-face medicine. Transitions to traditional medicine need to be smooth and efficient when the patient's needs can no longer be met by telemedicine. Providers, both initiating and consulting, must be trained initially and recurrently to maintain high-quality standards and to accommodate for new technologies. Organizational and administrative support in the form of business planning and operations, legal assistance, contracting, and marketing are important. Since telemedicine by its nature occurs between a patient and at least two providers and often in a very immediate fashion, the building and maintaining of relationships between providers is essential. Finally, telemedicine is a new and rapidly changing area of health care delivery for which there is no true "gold standard" or established "right way" to emulate. Those entering the world of telemedicine need to be flexible and creative and understand that constant troubleshooting and adjustment to changing situations are to be expected.

The problem of scale is unique to S&F telemedicine and is essentially the problem of matching capacity to demand. While a consultant can only physically see one patient at a time in their clinic or only be involved in one VTC at time, there is virtually no limit to how many S&F cases can be sent to a consultant in any period of time. When serving a large population of patients or a large number of referring providers, this can become a difficult workload problem. The potential answer to this problem lies in "scaling up" by creating a network of consultants, possibly geographically distant or time zone disparate, who can be recruiting in to handle heavy workload as needed. This is possible since telemedicine holds the possibility of routing workload to available providers without restriction by location or time zone. This model has been effectively applied by commercial teleradiology reading services.

Future Directions

The future in telemedicine is exciting. New technologies are rapidly emerging and will undoubtedly change the telemedicine space radically. High-definition technologies have already substantially upgraded the quality of VTC and will soon lead to enhanced ability to capture still images of extraordinary high quality. A new generation of home monitoring devices will result in telemedicine extending into the home of many patients and will change how care is delivered for chronic conditions and for preventive care. Improvements in broadband infrastructure should make telemedicine available to larger segments of the population and should improve its quality and speed. The ability to perform VTC over the Internet rather than over dedicated networks has already made VTC more available and has drastically dropped its cost. Finally, Accountable Care Organizations will have very strong financial incentives to reduce costs through the improved management of chronic disease, early diagnosis of conditions, and enhanced

provider efficiency. It is expected that telemedicine will be an important tool in the integrated care delivery plans for these organizations.

With the adoption of EHRs and emerging health information exchange networks, health care data will be made available for physicians located distances from the patients. Compilation of the information and remote access will indeed have an impact on telemedicine as practice workflows adopt and change.

Probably the most exciting future area of telemedicine is that of mobile health or mHealth. The use of mobile phones worldwide has undergone exponential growth in recent years. As networks become more available, faster, and able to accommodate more data, and as "smartphones" become more capable, their use for personal health care will undoubtedly explode in ways that most of us cannot imagine. This is already occurring with a large number of health-related "apps" coming on the market on a daily basis. Innovative health care systems are experimenting ways to leverage mobile phones to improve efficiency, outcomes, and customer satisfaction. The future consumers and providers of health care are technology savvy and will expect health care to be delivered in a way commensurate with their use and understanding of personal, mobile technology. The evolution of personal health records will further involve the patient in record collection, documentation, and care. It is possible that some day in the near future, "telemedicine" may become an archaic term referring to a past era when health care delivery and telecommunications and technology were somehow distinct and separate.

HIGHLIGHTS

- The three main areas of telemedicine are Interactive VTC, Asynchronous Store-and-Forward (S&F), and RPM.
- With regard to privacy and security standards, telemedicine should be treated no differently than an electronic health record.
- Telemedicine thus far has proven to be most useful in situations where there are remote populations to be served or a shortage of providers.
- Both S&F and VTC have been shown to have useful clinical applications in otology and neurotology.
- Reimbursement, credentialing, and professional liability related to telemedicine currently lack national standardization.

206 Quality Improvement in Otolaryngology

Rahul K. Shah *Jean Brereton* *David W. Roberson*

The otolaryngologist may sometimes feel that the word "quality" is used by everyone, in every situation, to address every issue and to mean whatever the speaker or writer wishes it to mean. The busy physician may be pardoned if he/she concludes that the term has no fixed meaning and that it is safe to tune out of any conversation where it comes up.

This chapter starts by trying not to define quality in medicine but to at least characterize it. We then make the case that, while the term is overused, there is a core set of principles and behaviors that can substantially improve the life of the otolaryngologist and his/her patients.

Quality in medicine refers to two very different, but complementary, things:

1. The rigorous measurement of actual outcomes and the use of that data to drive improvement
2. A set of principles and behaviors that have been shown to bring about improvements in a wide variety of diverse complex systems, including medicine and surgery

There is a large body of literature and practical experience about each of these domains. Much is known about how to measure real-world outcomes of complex processes, including medical and surgical care. Much is also known about how one can successfully bring about improvement in a complex organization (such as a physician practice, a hospital, or an operating room) (1).

Although the skills and practices needed for each domain are very different, it should be obvious that the two processes are complementary. If one sets out to improve a complex organization, it will be helpful to know whether the resulting outcomes are better, worse, or the same. Similarly, there is little if any value to measuring outcomes rigorously unless one has tools with which to improve low-performing organizations.

In order to provide a context for the quality improvement (QI) efforts within medicine, this chapter reviews the historical background for quality in surgery and medicine and the specific data in otolaryngology. Next, we describe the role of measurement for QI and discuss the organizations that are trying to create valid measures in medicine today and some of the current and future external standards for quality. We then discuss the performance of complex systems and how some organizations achieve high performance in complex systems and conclude with a very basic primer on how to engage in local QI.

HISTORICAL BACKGROUND

The concept of QI in medicine is not novel; some of our current-day practices were espoused by surgeons decades ago (2,3). Dr. Ernest Avery Codman (1869 to 1940) conceived of what he called "The End Result Idea" in Boston in the first decade of the 20th century (2,3). By rigorously following outcomes, he demonstrated that some surgeons far outperformed others and justified the need for specialization and extra training in specific surgical domains (2,3). He was essentially forced out of organized medicine and converted his home to a surgical hospital (2,3). It is impossible to know to what extent he was forced out because his ideas were threatening and to what extent his undiplomatic approach contributed. One high point of his not-so-subtle approach was distributing, at a meeting of the Boston county surgical society, a caricature of the Boston medical system that included (among other things) a caricature of the president of Harvard, musing "Could my clinical professors make a living without humbug?" (2,3).

Codman's work was later validated in many venues. He was one of the first surgeons to advocate for a surgical morbidity and mortality conference, now almost universal. He later chaired the committee for Standardization of Hospital for the American College of Surgeons—which ultimately morphed into the Joint Commission. Dr. Codman might be impressed with our surgical virtuosity and the technical

advances within our hospitals, but he would surely be extremely disappointed that most of us still do not follow the "End Result System" (2,3).

Much as the Flexner report in 1910 revolutionized and codified the medical education process, the Institute of Medicine's (IOM) 2000 report, To Err is Human, is seen by many as a watershed moment in our awareness of patient safety and quality (4). This report did not present any new data, but it did organize and synthesize the vast body of existing data on medical error and called it out publically and prominently. While some argued that the estimate of over 100,000 preventable deaths annually from extrapolated data from one state was unfair, subsequent research has generally indicated that the IOM report did "size" the problem reasonably accurately (4). The result has been a decade of tremendous contributions in the literature and actual improvement in outcomes for patients and hospitals. The initiatives have been broad based—from pediatrics to geriatrics and from private practices toward health systems.

QUALITY IN OTOLARYNGOLOGY: THE EVIDENCE IN OUR SPECIALTY

As noted above, some have doubted the conclusion of the IOM report, To Err is Human, about the number of errors and adverse events in American medicine. Specialty-specific data within otolaryngology have been generally confirmatory (5,6). A study of self-reports in a survey methodology revealed that approximately 2,500 preventable deaths occur annually in otolaryngology! (5). Aside from the mortalities, the study highlighted zones of risk for surgery. Specific areas where errors could be potentially ameliorated include zones of high risk, such as sinus surgery, surgery around major cranial nerves, use of concentrated epinephrine, and the immediate perioperative period (5). Targeted research has been performed to specifically address each of these areas and have further supported these areas as zones of risk.

Definitions

An *adverse event* is defined as a negative consequence resulting from medical treatment (4,7,8), and a *medical error* has multiple definitions, but the most broadly termed is an incorrect plan or failure to execute a correct plan (4,7,8). Some errors cause adverse events and some do not. Likewise, some adverse events are due to errors and some are not. For example, a patient with culture-positive streptococcal pharyngitis who is treated with amoxicillin and has anaphylaxis to the amoxicillin has experienced an adverse event, although there was no error. An error would be prescribing amoxicillin to a patient with a documented allergy to amoxicillin. This error might or might not lead to a reaction (an adverse event).

Currently, a great deal of effort is being put into reducing medical error. The goal is to reduce preventable adverse events (broadly defined as those adverse events which are due to errors). Adverse events not due to errors (e.g., mucositis from a correct dose of chemotherapy) might be considered unpreventable. However, this has not always proven to be true. When the senior author of this chapter (DWR) was a resident, ventilator-associated pneumonia affected about 10% of patients on ventilators, and was considered an unavoidable adverse event. With the advent of ventilator management bundles, ventilator-associated pneumonia has become quite rare in the United States. Thus the line between what is "preventable" and what is "unpreventable" may be at times unclear, and innovative thinking can allow us to prevent complications once thought unavoidable.

THE ROLE OF MEASUREMENT IN QI

There are two fundamental differences in the way that measurement is performed for QI purposes, compared to the measurement that is done for basic or clinical research (Tables 206.1 and 206.2):

1. For local improvement efforts, the overriding concern is that measurement should be inexpensive. Perfect accuracy and statistical significance are secondary considerations.
2. To compare physicians, hospitals, or health care systems, one needs not just measures but *metrics*—defined by Webster as "standards for measurement." All players need to measure something the same way in order for comparisons to be fair.

Most of us are trained to perform basic and/or clinical research. Extremely rigorous measurement, and an insistence on statistical validity, is the norm. In local clinical QI processes, the best measures are the cheapest ones—because you can afford to make them and afford to repeat them. When your practice introduces a new "check-in" form, you do not have the time, personnel, or money to study its effect with scientific rigor. Instead, you will use some type of "quick and dirty" measure of success. Often the measure will be as simple as asking your receptionist if it is working well. If it's not obvious there has been a change, you might go so far as to track check-in times for a couple of weeks. It would be foolish and wasteful to try to prove that the new form is better or worse with statistical significance. For ongoing improvement efforts, the major measurement consideration is opportunity cost, and one should strive for the simplest, roughest measure that will provide useful (even if imperfect) information. *One of the biggest obstacles to local improvement is the insistence on "scientific quality" data when "quick and dirty" measures should be used.*

TABLE 206.1 KEY DIFFERENCES IN MEASUREMENT IN RESEARCH VERSUS QUALITY: LOCAL QI EFFORTS

	Measurement for Local QI	
	Research	**Quality**
Measurement accuracy	*"Get it right"* Goal is perfect accuracy.	*"Spend wisely"* The resources for quality measurement are finite, and there are many important things to measure. Measuring something perfectly will usually take resources away from measurement of other important things. We should spend the least amount of money and human resources possible to get reasonably accurate information.
Data-based decision-making	*"Is $P < 0.05$?"* Clinical practice will not typically alter unless convincing statistical evidence builds up that a new treatment/process is better.	*"What do we think is the best decision?"* Quality is more like clinical medicine. Just as we must often make a clinical decision for a patient without perfect data, in quality, we often have to make decisions about our department and our processes without perfect data. If data are suggestive but not statistically significant that, for example, there is a problem or an area for improvement, the important question is not "Is $P < 0.05$?" but "Do we believe that this is concerning and we should do something about it?"
Follow-up	*"Next case"* There is no universal standard for performing follow-up research studies. Large studies are often elaborate, expensive, and only possible as "one-offs."	*"Never stop checking"* Important domains should be monitored forever since change can sneak in anytime. Ongoing monitoring provides a way of checking in case decisions made with imperfect data (see above) turn out to be wrong.

On the other hand, if your results are to be compared with your peers' results in public (e.g., on a government Web site), you would wish to insist on very rigorous measurement using fair, risk-adjusted data. When measures are used for comparison purposes, once again there is an important difference between the sorts of measures that most physicians are familiar with and the *metrics* that must be used for quality purposes. To compare different physicians or institutions, one must use rigorously defined metrics, in which every player uses the same definitions of (a) which patients are to be included, (b) what a "success" or "failure" is, and (c) exactly how the measurement will be performed. In addition, most metrics also require risk adjustment, since different physicians or hospitals may treat very different patient populations—and risk adjustment for many types of medical and surgical care is very difficult. But the point is that, under quality metrics, we are not free to define "success" or failure as we wish—everyone must work

TABLE 206.2 KEY DIFFERENCES IN MEASUREMENT IN RESEARCH VERSUS QUALITY: METRIC DEVELOPMENT

	Metric Development for "High Stakes" or Public Reporting and Comparison	
	Research	**Quality**
"Measurement" versus "Metric"	*"My way or the highway"* Each researcher must define for himself/herself how to measure clinical "success" or "failure." Rarely possible to compare fairly across institutions/settings.	*"Get on the bus"* Metric = "Standard for measurement" A metric is a rigorous definition of how to conduct a particular measurement. Only when different institutions agree on metrics can meaningful benchmarking take place. It is important to use accepted metrics, even if we do not feel they are the "ideal" definition.

with the same definitions. Naturally, it is rare that everyone agrees on what the correct metric is. Physicians, independent by nature, would often prefer to publish their personal definition of success in stapedectomy or cancer surgery. In clinical research this is normal, but in quality comparison metrics it completely defeats the purpose.

It is extraordinarily difficult to create good metrics for most clinical medicine and surgery. It is instructive to consider cases where metric development has succeeded and has indeed driven improvement.

One resounding success has been The Society of Thoracic Surgeons' surgical data registry, which now captures almost all cardiac cases done in the United States (9). This database has demonstrated significant variability between different hospitals and systems and served as a major impetus for improvement and reduction in postoperative mortality (9). The reasons that this database has been successful are that (a) cardiac surgeons repeatedly perform hundreds or thousands of very similar operations, (b) the vast majority of cardiac surgical complications are in just a few categories (death, cardiac arrest, stroke, venous thrombosis, and pulmonary embolus), and (c) cardiac surgery has a significant, measurable frequency of "nongameable" adverse events. It is easy to determine even from hospital administrative data if patients survived to discharge. Thus the measurement challenge, while very large, could be overcome with persistence.

Another huge success has been the sharing and distribution of data on cystic fibrosis (CF) outcomes. There is no question that this has spurred underperforming centers to improve and higher-performing centers to strive to "stay ahead," with the result that overall outcomes have improved considerably over the last decades (10). The reasons for this success are also similar. CF patients are almost all treated in CF centers; they usually spend most or all of their lives under the care of one center; there is an appreciable mortality (a non-gameable outcome) and an intermediate clinical outcome (FEV1) that is extraordinarily tightly linked to ultimate outcome (risk of death) (10). Therefore, CF centers can compare themselves to each other by looking at fairly simple measures of mortality and FEV1, with reasonable accuracy.

Consider how much more difficult it will be to compare two different otolaryngologists' performances at treating sinus disease. Major complications are extremely rare. Minor complications are highly "gameable"—it is difficult or impossible to determine with certainty whether or not every patient has a postoperative infection or transient bleeding. Few of us collect validated outcome data on our patients' results. There is no good risk-stratification system to indicate which patients are likely to be refractory to all treatment. Finally, the true measure of our success with sinus disease would measure how we do with all our patients—not just the ones who require surgery. The need to measure our performance at the medical aspect of management will be confounded by the fact that in some locations, the medical management is primarily done by allergists, internists, pediatricians, and family practitioners, while in other settings, the otolaryngologist may do much of the nonsurgical management. A measure that focused only on surgical outcomes, for example, would "reward" an otolaryngologist who performed unnecessary surgery on patients with mild, self-limited sinus disease. It is fallacious to argue, as some have done (footnote Porter and Teisberg, Redefining Health Care), that because measurement has improved care in relatively straightforward situations such as CF and cardiac surgery, it will be easy to extend this strategy to all conditions. Many national organizations, including the American Academy of Otolaryngology-Head and Neck Surgery (AAO-HNS), are working hard to develop valid metrics for many medical and surgical conditions, but the task is extremely difficult.

ORGANIZATIONS ENDORSING QUALITY MEASURES OR MEASURING QUALITY

There are myriad organizations, both public and private, that constitute the health care quality landscape. As many of these are involved in measuring, assessing, and reporting on physicians and the clinical care that they provide, we have included a brief description of some of the major entities tied to physician quality; however, this is not an exhaustive list, and, with the implementation of health care reform, the list will most certainly continue to expand. As of this writing (2011), it is fair to say that the national landscape of quality measurement organizations is cluttered. Some of these organizations will certainly survive; some may collapse or become superfluous; new ones may also be founded. An alphabetical listing of some of the important quality organizations on the national landscape, and a brief description of each, follows here.

Agency for Health Care Quality and Research

The Agency for Health Care Quality and Research (AHRQ) is a government agency within the Department of Health and Human Services that evaluates quality and safety in the delivery of health care, helps translate what works in health care, provides funding for health services research, and partners with both the public and private sectors in how to improve the health care delivery models.

Ambulatory Quality Alliance

The Ambulatory Quality Alliance (AQA) is a multi-stakeholder group (i.e., clinicians, health plans, consumer groups, employer groups) that is focused on improving quality and patient safety of health care in the outpatient setting. The group looks at the effectiveness of health care delivery by determining best practice in performance measurement, data integrity, and public reporting. The AQA is unique in that in attempts to have multi-stakeholders

convene, they can potentially align the stakeholders and secure broader-based support (11).

Centers for Medicare/Medicaid Services

As the government sponsored (Department of Health and Human Services) provider of Medicare and the oversight organization to State Medicaid programs, Centers for Medicare/Medicaid Services (CMS), the nation's largest insurer, was one of the earliest organizations to develop programs to assess quality in the provision of care and to evaluate the relationship between quality and cost (12). Beginning in the 1980s with the introduction of peer review organizations focused on inappropriate admissions and retrospective review of hospital length of stay, continuing with the adoption of QI organizations in the 1990s that focused on utilization of hospital services as a way to control costs, and most recently with the introduction of Pay for Performance, Compare Web sites, and the Physician Quality Reporting System, the government has been at the forefront of this movement toward the provision of high-quality, effective care with efficient use of resources.

Institute for Healthcare Improvement

The Institute for Healthcare Improvement (IHI) is a nonprofit Massachusetts-based institute that strives to optimize patient safety and outcomes. They are known for the tools and education they provide to health care professionals and the crucial role they play in assisting the prioritization of the myriad initiatives which exist. Indeed, they were so successful that Dr. Berwick, whom was president and chief executive officer of IHI, was recently appointed the head of the Centers for Medicare and Medicaid Services.

Institute of Medicine

The IOM is a nonprofit, nongovernmental organization dedicated to the improvement of health and health care. It is the organization within the National Academy of Sciences that responds to inquiries from governmental and private organizations on health policy issues. In 1999, the IOM produced the landmark report To Err is Human, a report that outlines how medical errors can be prevented and set a mandate to reduce errors by 50% over 5 years (4).

Joint Commission

As noted in this chapter, the Joint Commission can trace its root back to Dr. Codman, whom was always advocating for rigorous study of one's outcomes. At present, the Joint Commission serves many roles, the most prominent being a regulatory accrediting agency. In such a role, they have been pivotal in helping to advocate and push for real gains in transparency of outcomes, benchmarking, and tangible patient safety and QI metrics and results.

National Quality Forum

The National Quality Forum (NQF) is a private, nonprofit membership organization concentrated on establishing national patient safety priorities and performance improvement goals. NQF evaluates and endorses measures across a wide spectrum of specialties. NQF is contracted with the US Department of Health and Human Services to develop a process to evaluate and encourage measured development for the nation's top medical conditions, that is, those conditions that account for 95% of Medicare spending (13,14).

Physician Consortium for Performance Improvement

The American Medical Association formed the Physician Consortium for Performance Improvement (PCPI) in 2000 as the first physician-led initiative for the development of evidence-based measures, measure implementation, and outcomes reporting tools. PCPI membership includes representation from over 100 national medical societies and state medical societies as well as the AHRQ, the Council for Medical Specialty Societies, and the American Board of Medical Specialties (ABMS). To date, the PCPI has developed over 30 measure sets and close to 200 individual measures. PCPI measures represent the majority of measures contained with the Center for Medicare and Medicaid Services Physician Quality Reporting System.

Surgical Quality Alliance

The American College of Surgeons convened the Surgical Quality Alliance in 2005 to bring together over 20 surgical specialties (including Otolaryngology—Head and Neck Surgery) and anesthesia to address quality performance in surgery. The group ensures collaboration on quality measures across surgery and provides feedback to federal and private payer policy on issues addressing surgical quality of care (15).

EXTERNAL REQUIREMENTS FOR QUALITY

The ABMS sets the standards for 24 member boards for certification and maintenance of certification including for Otolaryngology—Head and Neck Surgery. In recognition that the boards play a major role in ensuring that physicians are continuously engaged in performance improvement over the course of their careers, they have developed a four-part framework for accessing physician competency (16). The four areas for physician assessment are *Part I* Licensure and professional standing, *Part II* Lifelong learning and periodic self-assessment, *Part III* Cognitive expertise as demonstrated through exam, and *Part IV* Performance in practice. By 2014 physicians must

demonstrate assessment of performance in practice and QI (every 2 to 5 years), the use of an approved survey tool that measures physician communication skills, and skill assessment through utilization of peer survey (17). Most medical boards now require physicians to demonstrate quality in their practice. There has been demonstrated value in such as improved outcomes have been associated with board certification/maintenance of certification (18).

QUALITY WITHIN HEALTH CARE INSTITUTIONS

Health System Programs

In response to market-driven competition and financial pressures from employers and payers, and most importantly, in the desire to provide, safe, high-quality care, hospital systems have been at the forefront of the QI movement. Hospitals develop QI programs that assess and measure physician performance across a multitude of clinical quality indicators. Much of this has been driven in response to external forces such as meeting Joint Commission standards, the public reporting of hospital-specific performance measures (CMS' Hospital Compare Web site and similarly from the Leapfrog Group), and pressures from government and private payers. Increasingly health systems executives and their respective boards are placing as much focus on clinical quality as has historically been placed on financial and operational data when assessing hospital performance. It has become clear that such importance to patient safety and quality also drives the financial metrics of the institutions. Hospital departments are being asked to provide specialty-specific measures as their hospitals embark on organization-wide QI programs, and performance on these measures is being taken into account in the development of physician compensation programs as well as for regulatory compliance with Ongoing Professional Practice Evaluation (OPPE) from the Joint Commission. Fortunately with the convergence of a robust information technology infrastructure in health care, much of these efforts and analysis have been made easier with continued implementation of electronic health records at the system level (19).

Department-Specific Initiatives

Starting in 2008, every health system was required to assess physician performance with regard to the six core competencies defined by the Joint Commission, the ABMS, and the American Council for Graduate Medical Education. Previously, these six areas of assessment were utilized solely in the assessment of house officers, but the Joint Commission has now extended these requirements to every physician on a hospital's medical staff. Called the OPPE, the core areas measured are Medical/Clinical Knowledge, Patient Care, Interpersonal Skills and Communication, Practice-Based Learning, Professionalism, and System-Based Practice. If there are issues identified with individual physician performance or if a physician is new to the hospital or is seeking privileges for a procedure, the physician may be assessed utilizing a Focused Professional Performance Evaluation (FPPE), a time-limited period during which an organization evaluates and determines a practitioner's performance in practice. This can be done through chart review, monitoring practice, simulation, or peer review. As these tools, the OPPE and FPPE, are relatively new introductions for physicians to assess quality, there will certainly be iterations to such as the specific measurement tools are developed and trialed (20).

QUALITY AND REIMBURSEMENT

While there have been many gains in quality particularly in the prior couple of decades, improvements have mainly been focused within individual hospitals and health systems and related to specific conditions. For instance, the Joint Commission reported that scores on meeting quality parameters for heart attack, pneumonia, surgery, and childhood asthma rose from 81.8% to 95.4% between 2002 and 2009 (21). However, there has not been consistent, widespread improvement over many health conditions in inpatient and ambulatory health settings (22). To speed the journey and increase the consistency over time of health QI, many hospitals and insurers, including Medicare, have tied improvement in quality metrics to financial incentives associated with compensation (salary incentives) or through enhancements to reimbursement for services rendered (e.g., Pay for Performance programs and CMS' Physician Quality Reporting System). Most of these programs focus on evaluating physician performance across a broad set of measures including those derived from medical records, billing and administrative data, electronic health records, and patient and provider surveys. It is not yet clear to what extent financial incentives can drive fundamental, long-term changes in behavior and health systems, and other physician organizations are looking at a number of approaches (i.e., peer review, public reporting, financial incentives), which taken together may potentially drive lasting change (23).

QUALITY AND HEALTH CARE REFORM

When discussing reform of any nature, it is with caution that the three issues below are highlighted as it maybe, a decade from now, these entities may not even exist or may have been substantially changed by legislation in their scope, etc. In 2010, the Patient Protection and Healthcare Affordable Care Act was signed into law. The act is designed to make significant changes to the delivery and financing of health care in the United States. The goal of health care reform is to eliminate the fragmentation of the current health delivery system and improve health care effectiveness and quality while slowing spending. Two of the major tenets of the legislation were the creation of accountable

care organizations (ACOs) and creation of the CMS Innovation Center. The act sets forth the Medicare Shared Savings Program for ACO. What is envisioned is an organization (physician led or hospital) that takes accountability for a set group of Medicare patients and, based on delivering high-quality care and reducing the cost of that care below expected levels, can share in the realized savings. It is anticipated that ACOs could aid in reducing the fragmentary nature of the current health care delivery model and provide vertical integration of care rather than the more traditional horizontal integration of care. The concept is different from shared risk arrangements of the past in that there are built in safeguards against downside risk at least for the initial years of the arrangement. Many of the details of how ACOs would be structured and who will fund the necessary upfront costs have yet to be fully addressed (24). The act also stipulated the creation of the CMS Innovation Center that will create new payment and health services delivery models designed to reduce cost while maintaining and enhancing quality of care. The initial focus of the Innovation Center will be the Partnership for Patients that has the dual purpose of (a) reducing health care–acquired conditions 40% from 2010 to 2013 and (b) reducing hospital readmissions 20% during this time period. It is estimated that in meeting these two measures alone, 60,000 lives could be saved and many complications of care eliminated. The financial impact is purported to be as much as $50 billion in savings over ten years (25).

COMPLEX SYSTEMS AND HIGH PERFORMANCE WITHIN SYSTEMS

Dr. Avedis Donabedian (1919 to 2000) laid the foundation for an understanding of systems science applications to health care QI. His significant contribution was the concept of the framework for QI that included structure, process, and outcome. Much of the organizational QI processes in health care come from his prescient teachings. Systems science is the fundamental concept that in health care, the delivery of care is made up of overlapping systems. These systems interact to ensure the patient is cared for. For example, a critically injured child in a motor vehicle accident is triaged by an emergency medicine team (system) that brings the child to the hospital (system), where the child is managed by the trauma team (system) that decides the patient needs to have surgery (system) and the patient is whisked to the operating room and managed by a cadre of health care professionals (system) that successfully operates on her, and she recuperates on the ward (system) to be discharged without issue back to her home (system).

The myriad systems that one encounters mandate that we consider health care organizations to be amenable to application of concepts of systems science. A spectrum exists as there are, of course, those systems that are exemplars and others that barely function. The later are easy to conjure; the most successful systems include the nuclear industry, airline industry, and chemical manufacturing. Unfortunately, health care lies in the middle of such spectrum. In an effort to imbue health care, specifically, otolaryngology, which such characteristics, it is imperative to identify such so that we can learn from other industries. Systems that function at a very high level with consistent reliability are called high-reliability organizations or high-performance systems. Characteristics of such systems include many variables, the most pertinent to otolaryngology include (1) an understanding that (a) common aims are essential, (b) outstanding systems are created from outstanding elements, (c) complex systems are inherently unpredictable, (d) feedback loops improve performance, (e) standardization improves function for repetitive processes, (f) standardization is the only baseline, (g) shortened cycle time improves function, (h) system features should be driven by system goal, (i) human error is ubiquitous, (j) respect for persons improves systems performance, and (k) strong constructive leadership is essential. A failure by physicians, especially otolaryngologists, to embrace and understand the nuances of high-performance systems will result in inefficiencies and frustrations. An excellent cognitive process is to choose one of the identified characteristics of high-reliability organizations above and apply it to your realm and see the outcomes. For example, try dictating and signing charts immediately—the downstream effects in terms of improved communication, improved patient care, and ultimately outcomes will be eye-opening.

A PRIMER ON LOCAL QI INITIATIVES

It is imperative for surgeons to lead QI initiatives as we are presumably the experts of our patients. However we are not experts on QI projects, as such, in large or academic health systems, you may be able to partner with your patient safety and QI offices. In smaller hospitals or practices, you may have to design your own initiatives. With any QI project, it is important to start small and periodically measure the effect of the intervention. A basic and classic model for a QI initiative is the PDSA cycle. This involves the steps of (P)lanning an intervention, (D)oing the intervention, (S)tudying the impact of the intervention, and (A)cting to improve the outcomes further. This iterative cycle is one of the most basic QI tools.

Nationally, with regard to otolaryngology, there are several anecdotal best practices that have been implemented as QI initiatives. Some of the standout projects include calling posttonsillectomy patients back instead of having them come back to the office for follow-up (26). An example that is not in the peer-reviewed literature was a practice in which, after misadministration of allergy sera to the wrong patient with an untoward outcome, the practice implemented a check where the patient corroborates with the technician that he or she is going to receive the intended allergy sera.

CONCLUSION

"Quality," properly understood, refers to two different but complementary sets of activities:

1. The use of basic, well-known principles to improve processes locally
2. The rigorous measurement of outcomes and the use of that data to drive improvement

The two processes require very different actions and skill sets, but are highly complementary. Every physician should understand the basics of local QI, and every physician should understand what distinguishes local improvement measures from rigorous national metrics. Not every physician can or should be expert in national outcome metrics; it is critical that physicians as groups (e.g., through national specialty societies) are engaged in the process of developing, validating, and deploying national metrics.

HIGHLIGHTS

- There is potential for significant benefit from implementation of QI initiatives in otolaryngology.
- There are fundamental differences in the way that measurement is performed for QI purposes, compared to the measurement that is done for basic or clinical research.
- Nationally, there are several quality organizations that are driving the initiatives on a broad level.
- Quality in medicine can be achieved by application of systems science principles to move organizations toward high-reliability organizations.
- Local QI efforts are easily implemented and can be done successfully by following the (p)lan, (d)o, (s)tudy, and (a)ct cycle.

207 Conflict of Interest

Andrew H. Murr *Susan J. Murr*

The views expressed in this chapter are the personal views of the authors and do not represent the views of their respective employers.

Conflicts of interest between physicians and industry have received much attention in the headlines lately, perhaps driven by the increasing complexity of potential relationships. Relationships between the physician community and industry are important in helping patients through the development of new medicines and technologies that enable patients to live longer and healthier lives. In short, these relationships are essential to medical innovation. At the same time, these relationships must be managed in a transparent, ethical manner to insure that first and foremost, the best interests of the patient are kept in the forefront. This chapter explores the definition of a conflict using examples from the news, the types of relationships that may pose conflicts, some of the rules governing conflicts, and best practices in the management of conflicts.

DEFINITION OF CONFLICT OF INTEREST

The definition of conflict of interest is variable, but according to Merriam-Webster's online dictionary a conflict of interest is "a conflict between the private interests and the official responsibilities of a person in a position of trust" (1). This conflict may commonly be based upon financial rewards, but it can also be based upon a set of circumstances that achieves a specific outcome. An example of an outcome as a component of a conflict of interest is when a judge must excuse himself or herself because of a type of knowledge or relationship that is possessed that may then skew or give the appearance of skewing the outcome of a legal case. Another term, duality of interest, is used when a person has two roles, which may lead to an influence on judgment. An example of duality of interest is when a board member of a foundation that gives research grants is also part of a team that has applied for one of the foundation's grants.

Several examples of possible perceived conflicts of interest have been prominent in news reports over the past several years, and these examples can be instructive. In 2009, Liz Kowalczyk of the Boston Globe wrote an article about a potential conflict of interest at Massachusetts General Hospital involving Dr. Joseph Biederman who oversaw a study involving risperidone in treating psychosis in children under age 10 between 2002 and 2005. Johnson and Johnson, the company that manufactured the drug via Janssen Pharmaceuticals, had given $700,000 to support the research center at Massachusetts General, and it was reported that Dr. Biederman appeared to have received $1.5 million in consulting and speaking fees from them. This income was allegedly not reported in a timely fashion to Harvard University. Although Dr. Biederman did not own stock in J&J, J&J was alleged to be intimately involved in the research center that Dr. Biederman oversaw. As Dr. Marcia Angell summarized in a comment for the Boston Globe on March 20, 2009, "Even if you have the best intentions, it's hard to remain objective about people who've been so good to you" (2). Whether or not the income and support from J&J influenced the outcome of ongoing research work is unknown. However, large amounts of monetary support for studies in the form of research center support and income and consulting fees can have the appearance of influencing the accumulation of objective results.

Another story depicting a possible conflict of interest involved the development and marketing of an orthopedic hip implant manufactured by DePuy. The implant was developed by several physicians including Dr. Thomas Schmalzried and Dr. Thomas Vail and was known as the ASR Implant. The implant was released in the United States in 2005 without undergoing FDA trials after being used abroad, but by 2008 there were over 200 problems reported with the implant, and by 2009 over 300 problems were reported. A high percentage of reported problems resulted in a need to replace the implant. DePuy was reportedly slow to react to information about problems with the

product and continued to market the device. The developers of the device were also reported to be supportive of it even in the face of mounting failure data. Dr. Schmalzried was reported as receiving $3.4 million in payments over a 2-year period for work and royalties related to the device. The company and the physicians were accused of continuing to support the device after data showed it to be failing at a high rate. Finally, DePuy pulled the device from the market (3). Taking this information at face value, news reports speculated that it appeared that financial incentives and profit may have interfered with timely decision making in light of accumulating negative clinical information concerning the clinical performance and failure rate of the device in which the doctors had a financial interest (4).

The main tool used to combat the appearance of conflict of interest is disclosure. Disclosure allows a person with a potential conflict to report the issue prior to beginning work on a study or publication or presentation. In this way, any judgmental body such as an editorial review board or an audience at a lecture can be apprised of the relationship of an individual to a technology or drug or research question. Disclosure also allows the possibility of screening slides or other presentation material by a disinterested third party to make sure that biased information is not being disseminated in a scientific or educational setting that awards educational credits to people who are in the audience. Obviously, one way to control conflict of interest in presented material would be to have a zero tolerance approach whereby any person who has any financial or other interest in a project or outcome would not be welcome to participate in publically speaking or writing about the subject. This extreme position, however, would essentially be a prohibition upon allowing some of the most creative and expert scientists and investigators from being involved in the education process. It would also deter experts from becoming involved in promising investigations that could have translational and commercial applications. Certainly, translational science should be encouraged and not discouraged as the benefit to society as a whole is an overriding principle. As a result, conflict of interest can be managed through a process of transparency rather than being prohibited outright.

CONFLICT OF INTEREST IN PUBLISHING

Because of variability in defining conflict of interest, each journal or publication theoretically can define its own individual set of standards for its authors and readers. Standardization, however, certainly has some advantages. The International Committee of Medical Journal Editors (ICMJE) has recently adopted a standard form for disclosure formally referred to as "ICMJE Form for Disclosure of Potential Conflicts of Interest" (5) (Fig. 207.1). This form has been embraced by many journals including JAMA (6,7). The form is a fairly simple PDF document that has four sections. Section 1 is identifying information. Section 2 elicits information about personal or institutional payment from a third party to support any aspect of the submitted work. This includes grants, consulting fees, travel support, fees for data monitoring or statistical analysis, fees for writing or reviewing the work, writing assistance or administrative support, or others. Section 3 probes financial activities outside of the submitted work, including relationships present during the 36 months prior to the actual submission. This includes board memberships, consultancies, employment, expert testimony, grants, payment for lectures, payment for manuscript preparation, patents, royalties, payment for developing educational presentations, stock options, travel accommodations and meeting expenses, or other. Finally, Section 4 asks for any other relevant information that the author can think of that may have influenced the work. Section 4 was added after a period of review and comment elicited feedback that itemizing every conceivable conflict, such as conflicts involving spouses or children, is impractical. To resolve this challenge, Section 4 was added as an open-ended section to allow the author to submit any other potential category of conflict that had been missed in the above sections (6). Not every otolaryngology—head and neck surgery–based journal has adopted this ICMJE form, but the thoroughness and thoughtfulness of this form is a relatively concise guide to what would be expected in disclosing all aspects of potential bias when submitting an article for publication consideration.

CONFLICT OF INTEREST IN RESEARCH

Recently, the National Institutes of Health (NIH) proposed the first major overhaul of conflict of interest guidelines in over a decade. Old standards triggered financial reporting at $10,000. The new guidelines require disclosure of support that exceeds $5,000. This includes reporting stock ownership, speaking fees, consulting arrangements, and other financial relationships with foundations or industry. Disclosure of these potential conflicts is to be made to the parent institution, and so the parent institution is therefore tasked with monitoring compliance with ethical standards. The parent institution is also responsible for allowing public scrutiny of any reported disclosure items. As a dual check on reporting, the Patient Protection and Affordable Care Act, commonly known as the Obama Health Care Plan, also included a "sunshine provision" that mandated that industry report to a government database any payment or gift to a physician greater than $10 (8,9).

INSTITUTIONAL CONFLICT OF INTEREST

Individuals are not the only people who can benefit from financial arrangements with industry. Very often, entire institutions have a stake in a certain technology or drug. A case in point involved a situation at the Cleveland Clinic. According to news reports, Delos M. Cosgrove, M.D., was the head of the Cleveland Clinic Foundation and had received royalties from a company called AtriCure.

ICMJE Form for Disclosure of Potential Con□icts of Interest

Instructions

The purpose of this form is to provide readers of your manuscript with information about your other interests that could in□uence how they receive and understand your work. The form is designed to be completed electronically and stored electronically. It contains programming that allows appropriate data display. Each author should submit a separate form and is responsible for the accuracy and completeness of the submitted information. The form is in four parts.

1. Identifying information.

Enter your full name. If you are NOT the corresponding author please check the box "no" and a space to enter the name of the corresponding author in the space that appears. Provide the requested manuscript information. Double-check the manuscript number and enter it.

2. The work under consideration for publication.

This section asks for information about the work that you have submitted for publication. The time frame for this reporting is that of the work itself, from the initial conception and planning to the present. The requested information is about resources that you received, either directly or indirectly (via your institution), to enable you to complete the work. Checking "No" means that you did the work without receiving any □nancial support from any third party -- that is, the work was supported by funds from the same institution that pays your salary and that institution did not receive third-party funds with which to pay you. If you or your institution received funds from a third party to support the work, such as a government granting agency, charitable foundation or commercial sponsor, check "Yes". Then complete the appropriate boxes to indicate the type of support and whether the payment went to you, or to your institution, or both.

3. Relevant □nancial activities outside the submitted work.

This section asks about your □nancial relationships with entities in the bio-medical arena that could be perceived to in□uence, or that give the appearance of potentially in□uencing, what you wrote in the submitted work. You should disclose interactions with ANY entity that could be considered broadly relevant to the work. For example, if your article is about testing an epidermal growth factor receptor (EGFR) antagonist in lung cancer, you should report all associations with entities pursuing diagnostic or therapeutic strategies in cancer in general, not just in the area of EGFR or lung cancer.

Report all sources of revenue paid (or promised to be paid) directly to you or your institution on your behalf over the 36 months prior to submission of the work. This should include all monies from sources with relevance to the submitted work, not just monies from the entity that sponsored the research. Please note that your interactions with the work's sponsor that are outside the submitted work should also be listed here. If there is any question, it is usually better to disclose a relationship than not to do so.

For grants you have received for work outside the submitted work, you should disclose support ONLY from entities that could be perceived to be a□ected □nancially by the published work, such as drug companies, or foundations supported by entities that could be perceived to have a □nancial stake in the outcome. Public funding sources, such as government agencies, charitable foundations or academic institutions, need not be disclosed. For example, if a government agency sponsored a study in which you have been involved and drugs were provided by a pharmaceutical company, you need only list the pharmaceutical company.

4. Other relationships.

Use this section to report other relationships or activities that readers could perceive to have in□uenced, or that give the appearance of potentially in□uencing, what you wrote in the submitted work.

Figure 207.1 ICMJE disclosure form. This ICMJE disclosure form is designed to provide transparency with regard to any conflicts an author might have in developing material for publication. It succinctly covers most issues likely to be encountered when considering conflict of interest.

ICMJE INTERNATIONAL COMMITTEE of MEDICAL JOURNAL EDITORS

ICMJE Form for Disclosure of Potential Con☒icts of Interest

Section 1. Identifying Information

1. Given Name (First Name) 2. Surname (Last Name) 3. E☒ective Date (07-August-2008)

4. Are you the corresponding author? ☐ Yes ☐ No

5. Manuscript Title

6. Manuscript Identifying Number (if you know it)

Section 2. The Work Under Consideration for Publication

Did you or your institution at any time receive payment or services from a third party for any aspect of the submitted work (including but not limited to grants, data monitoring board, study design, manuscript preparation, statistical analysis, etc…)?

Complete each row by checking "No" or providing the requested information. If you have more than one relationship click the "Add" button to add a row. Excess rows can be removed by clicking the "X" button.

The Work Under Consideration for Publication

Type	No	Money Paid to You	Money to Your Institution*	Name of Entity	Comments**	
1. Grant	☐	☐	☐			×
						ADD
2. Consulting fee or honorarium	☐	☐	☐			×
						ADD
3. Support for travel to meetings for the study or other purposes	☐	☐	☐			×
						ADD
4. Fees for participation in review activities such as data monitoring boards, statistical analysis, end point committees, and the like	☐	☐	☐			×
						ADD
5. Payment for writing or reviewing the manuscript	☐	☐	☐			×
						ADD
6. Provision of writing assistance, medicines, equipment, or administrative support	☐	☐	☐			×

12. Travel/accommodations/ meeting expenses unrelated to activities listed**	☐	☐	☐			×
						ADD
13. Other (err on the side of full disclosure)	☐	☐	☐			×
						ADD

* This means money that your institution received for your efforts.
** For example, if you report a consultancy above there is no need to report travel related to that consultancy on this line.

Section 4. Other relationships

Are there other relationships or activities that readers could perceive to have influenced, or that give the appearance of potentially influencing, what you wrote in the submitted work?

☐ No other relationships/conditions/circumstances that present a potential conflict of interest

☐ Yes, the following relationships/conditions/circumstances are present (explain below):

At the time of manuscript acceptance, journals will ask authors to confirm and, if necessary, update their disclosure statements. On occasion, journals may ask authors to disclose further information about reported relationships.

Evaluation and Feedback

Please visit http://www.icmje.org/cgi-bin/feedback to provide feedback on your experience with completing this form.

Figure 207.1 *(Continued)*

AtriCure produced a surgical tool that was not specifically FDA approved for heart surgery in 2005, but the Cleveland Clinic had been conducting research on using the tool to ablate atrial fibrillation. The Cleveland Clinic itself apparently also had an investment interest in the company. Yet, in conducting the research, patients were not initially made aware of the institution's financial interest and the foundation director's financial relationship to the technology. Eventually, Dr. Cosgrove removed himself from overseeing the Cleveland Clinic Foundation's investment section, and the institution created the Cleveland Clinic's Innovation Management and Conflict of Interest Committee to vet promising technologies and their relationship to the organization (10). Thus, Cleveland Clinic developed an individual approach to managing the institution's expertise, creativity in translational research, and economic investments in a presumably ethical fashion. Other organizations such as the American Association of Medical Colleges and the Institute of Medicine (IOM) have constructed guidelines and recommendations to allow institutions to ethically manage conflict of interest while still benefiting from expertise in translational research and industry partnerships (11). Uniformity in adopting these guidelines has been relatively unsuccessful as recently shown in a report published by Ehringhaus in Journal of the American Medical Association, which showed that only 38% of institutions had policies which oversaw the institution's own investment portfolio (12).

CONFLICT OF INTEREST IN MEDICAL PRACTICE

Conflicts of interest can be encountered in the direct delivery of health care. The federal government has identified this potential conflict and has through the legislature weighed in by developing laws that concern direct medical practice.

Although beyond the scope of this chapter to discuss in detail, the prohibition on collective bargaining by physicians by the federal government certainly has its roots in a valuation judgment concerning conflict of interest. The idea that physicians would "price fix" is deemed to be in direct conflict with societal well-being, presumably. More directly, the federal Stark legislation has developed rules to prevent physicians and practices from directly referring business to entities in which they have a financial interest. The Stark legislation was passed in three parts: Part I in 1989, Part II in 1993, and Part III became effective in 2007. Obviously legislation of this sort is complex and subject to interpretation and opinion and judgment. In general, Part I addressed the issue of physicians referring laboratory work to laboratories in which they had a financial interest. Part II addressed other medical practice venues and also set aside exceptions or "safe harbors." One particular exception was in the development of outpatient surgicenters. Finally, Part III was signed into law by President Clinton as part of Medicare legislation and contained an "antikickback" provision so that referrals to a center of care could not result in a financial bonus to the physician who made the referral. Also, these laws are designed to govern Medicare and Medicaid billing issues (13–16). Another area of conflict of interest in direct medical practice has to do with complicated rules governing the submission of bills to the government Medicare program. The federal government has often claimed that fraudulent billing in the Medicare system is a source of financial waste and ill-gotten gains. In the 1990s under the Clinton administration, PATH audits were accomplished. PATH stands for "Physicians At Teaching Hospitals." The government's position was that Medicare Part A dollars paid for resident salaries. Because the resident salaries were supported partly by these Part A dollars, any further billing for services provided by residents were considered to be duplicative. Therefore, overseeing faculty could not bill for resident services under Part B of Medicare unless they were actively taking part in direct teaching or supervision of the work. In general, direct patient care services are billed through Medicare Part B in all practices that participate in this government program.

Financial conflicts of interest in the government system became apparent in three general categories during PATH audits. One category was when a physician billed for a service that was not at the correct level of complexity. Billing levels were generally divided into five categories of complexity on the outpatient side of medicine, and reimbursements were made by higher amounts or remuneration as the complexity of the patient encounter, time spent, and decision making increased. Audits were directed to determine if the amount billed was consistent with the documentation that described the visit. If the documentation did not match the billing level, fines and penalties could be assessed. A conflict of interest was therefore inherent between the physician's desire to be maximally reimbursed at the discounted Medicare rate and the documentation that the physician could provide to support the level of service claimed. A second category of investigation pertained to procedural billing. A system was developed to valuate the relative complexity and worth of various surgical and other procedures. The concept of a Relative Value Unit, or RVU, was invented to provide a basis for creating a differential financial value scale that could be applied to various interventions in surgery and medicine. A conflict of interest would exist if a surgeon billed for a certain procedure that was more complex and more highly valued while a less complex or valued procedure was actually performed. The third category of conflict of interest addressed the problem of a supervising physician billing for a service that was accomplished by a resident while the attending physician was not properly present to supervise or accomplish the procedure in person.

An example of the power inherent in the federal government's ability to conduct an audit is reflected in the experience of H. Richard Winn, the former Chief of

Neurosurgery at University of Washington. As he reports in the *Journal of Neurosurgery*, Dr. Winn was the subject of a detailed investigation by the federal government. He was accused of improperly billing Medicare for services rendered by residents who were not properly supervised as well as several other charges. The final outcome was that Dr. Winn pleaded guilty to "one count of obstructing 'communication of information to a criminal investigator'" after a 3-year federal investigation. A $500,000 fine was also levied, which "represented 0.5% and 1.3% of billings and revenues, respectively." The institution itself was also the subject of controversy for not properly educating its faculty on the nuances of proper billing procedures. Dr. Winn left the University of Washington and was required to write an account of the audit, which revealed errors in compliance with federal rules which was published in the *Journal of Neurosurgery* (17). The stakes for maintaining an appropriate compliance with federal regulations governing conflict of interest and economic practices are quite high.

CONFLICT OF INTEREST IN CONTINUING MEDICAL EDUCATION

Continuing medical education (CME) programs are designed to deliver credits to learners who participate in enhancing their knowledge and competency to practice medicine. CME credits are typically required to renew medical licensure. The Accreditation Council for Continuing Medical Education (ACCME) is the governing body that accredits institutions to oversee and run CME programs. Conflict of interest can be part of this process in two general categories. First, individuals invited to speak at a program may have worked on a technology in which they have a financial interest, which can impact the objective presentation of information. Second, companies often support programs through contribution of funds, which help to underwrite the event. This may come in the form of direct support for the program activity or in the form of paying to be able to set up a marketing display at the event. Marketing displays must be physically separated from the presentation of educational material.

Each organization that runs an event for credit must have a policy that governs these conflicts in accordance with oversight of the ACCME. The ACCME requires that all individuals in a position to oversee the educational content of a CME event disclose any "relevant financial relationships." The financial conflicts of interest may be in any amount occurring within the last 12 months. To be pertinent, relevant conflicts of interest must also affect the content of the presentation. Relevant conflicts also include financial or other interests held by a spouse or partner. Individual institutions must develop a specific policy on faculty disclosure and an oversight process to vet disclosures. Valid disclosure typically pertains to salary, royalties, intellectual property rights, consulting fees, honoraria, ownership interest, employment or management positions, speaking fees, consulting fees, or advisory panel, review panel, or board memberships. If such a relationship is identified, it is still valid for a speaker to deliver content at a CME meeting as long as the presentation and/or slides are reviewed in advance by a person who is impartial. The validation process generally includes review of literature cited to make sure it is objective, surveying the presented information to assure balance, and assessing the presentation to assure that it is nonpromotional (18).

SPECIFIC RULES GOVERNING CONFLICTS IN INDUSTRY

The topic of rules governing conflicts of interest between industry and the medical profession is complex, as requirements can take many forms. In this emerging area, requirements can come from many different sources. This section provides an overview of some of these requirements. The intention is not to be all-inclusive, which in this rapidly developing area is not possible, but instead to help raise awareness of the potential sources for and common types of these varying requirements.

At the federal level, the antikickback statutes require that industry not provide unlawful inducements to health care professionals for the purchase of products. The antikickback statutes prohibit for the health care industry some practices which may be common in other industries. These statutes contain criminal prohibitions against payment (or the solicitation of payment) in any form, whether direct or indirect, for the referral or purchase of any item or service that is reimbursable under a federal health care program. As such, their scope is broad (19).

These requirements are further illuminated in the Office of Inspector General for the U.S. Department of Health and Human Services (OIG) Compliance Program Guide for Pharmaceutical Manufacturers. This guide provides practical examples in many areas of activity, including discounts, product support services, educational grants, research funding, business courtesies (entertainment, travel, meals, gifts, etc.), and samples. As such, the guide provides a road map to industry and the physician community of the types of activities that may be risky or prohibited as applied to the vast array of different types of health care professionals' relationships with industry (20).

The pharmaceutical and medical device industries have also been self-policing, with trade associations and their members adopting the Code on Interactions with Healthcare Professionals (PhRMA Code) and Code of Ethics on Interactions with Health Care Professionals (AdvaMed Code), respectively (21,22). These codes are meant to provide a practical framework by which industry can maintain compliance with the complex requirements of the federal antikickback statutes, among others. These codes not only require industry to maintain a compliance program but provide practical guidance in the areas of product training and education, educational conference

support, sales, promotional and business meetings, consulting arrangements, royalty payments, prohibitions on entertainment and recreation, guidelines for modest meals, educational items and prohibitions on gifts, provision of coverage, reimbursement and health economics information, research and educational grants and charitable donations, and evaluation and demonstration products. The two industry codes cover industry behavior and differ slightly in content, taking into account the differences between the two industries, which is why medical device sales representatives and pharmaceutical sales representatives may interact with health care professionals in slightly different ways.

States have increasingly begun to promulgate legislation in the area as well, with requirements aimed at industry behavior. These requirements typically take one of two forms: (a) conduct requirements that regulate manufacturer's interactions with health care professionals and (b) disclosure requirements that require manufacturers to report the amount of certain spending, such as consulting agreements, provision of educational items, meals, and product training, among other things, to certain recipients including physicians. Some states require both conduct and disclosure requirements and in several instances those conduct requirements in effect codify, or make into law, the existing industry codes. There are currently 10 jurisdictions that have laws in this area. California, Connecticut, Massachusetts, Minnesota, Nevada, and Vermont have conduct requirements, while Colorado, Maine, Massachusetts, Minnesota, Vermont, Washington DC, and West Virginia have public disclosure requirements (23).

In addition to state law, a relatively unpublicized provision of the Obama administration's health care reform, the Patient Protection and Affordable Care Act, commonly referred to as the "Sunshine Act," extends disclosure requirements at the federal level to physicians and teaching hospitals while including some conduct requirements as well. Effective January 1, 2012, pharmaceutical and medical device companies will need to collect and report payments to physicians and teaching hospitals for consulting fees, compensation for services, honoraria, gifts, entertainment, food, travel, education, research, charitable contributions, royalty or license fees, ownership or investment interest, speaker fees, grants, and anything else defined in the regulations. These requirements are sweeping and reports will be done at the individual recipient level to provide greater transparency of these relationships, which will be published by the federal government on a publically available and searchable database (24).

Conflict of interest rules are not confined to industry. CME has long been overseen by ACCME, which provides strict requirements to help insure that CME programs are fair, balanced, and independent of commercial bias and influence, while still allowing industry support (25). ACCME requires that commercial support associated with any CME activity be given with full knowledge of the educational provider. Social events associated with CME activities must be subordinate to the educational component of the meeting. Product promotion is prohibited during the CME activity and any promotional activity or product advertisement must occur in a space separate from the educational event space. In this manner, CME events can provide objective information that can be used by physicians to independently evaluate practices and procedures without the shadow of any actual or perceived conflicts with industry, while allowing industry to continue to provide valuable support of educational events.

Medical societies have also gotten into the act. For example, the Council of Medical Specialty Societies in April 2010 developed a Code for Interactions with Companies (26). These guidelines apply to the individual specialty societies that belong to the council and establish core principles to help minimize actual or perceived conflicts of interest. The principles for interaction with industry include independence, transparency, accepting charitable contributions, accepting corporate sponsorships, society meetings, research grants, clinical practice guidelines, journals, advertising, and licensing. In this manner, by setting standards which medical specialty societies can adapt and adopt, the council helps to ensure that society members' interactions with companies remain focused on the benefit of patients and members and the improvement of patient care.

Likewise, the American Academy of Orthopedic Surgeons (AAOS) has recently developed some new disclosure rules, which are notable in requiring public disclosure and providing a publically available searchable online database. In announcing the new database in December 2009, AAOS acknowledged that it is responding to increasing public and government scrutiny of the relationship between orthopedic surgeons and industry. The enhanced policy requires each participant in an AAOS CME program, or author, and members of AAOS governance groups to disclose all potential conflicts of interests. Using a uniform format, these participants are responsible for recording their relationships with commercial entities relating to orthopedics and must review and update this information at least semiannually. Information to be provided includes royalties, speakers bureaus, industry employment, consulting (paid or unpaid), stock options, research support, and other financial support. Failure to participate can result in the physician being asked to not participate in the program or governance group. The information in the AAOS Orthopaedic Disclosure Program is available both to members and to the public, and individual disclosures are included in meeting materials (27).

The American Academy of Otolaryngology—Head and Neck Surgery has promulgated a Statement of Principles and Code of Ethics (Code) that succinctly addresses industry relations:

> "This Code of Ethics does not seek to restrict legal trade practices. However, a physician's commercial or financial interests should never be placed ahead of the interests and welfare of patients. Conflicts of interest undermine the trust that patients place in their physician. For this reason, physicians should endeavor to avoid any venture that creates a conflict of interest between personal financial interests and the best interests of the patient. Conflicts that develop between a physician's financial interests and the physician's responsibilities to the patient should be resolved to the benefit of the patient."

The Code also covers inventions and fee-setting, among other topics (28).

Institutions are also developing conflict of interest and disclosure requirements—and are making headlines as they do so. In late 2008 the Cleveland Clinic led the way by becoming the first major medical center to announce that they would be making a complete disclosure of doctors' and researchers' financial ties to industry on their Web site (29). In 2009 Harvard University–affiliated hospitals adopted new conflict of interest guidelines, which forbid industry gifts and ban meals and doctors' participation in speaker programs (30). Harvard Medical School has followed suit, banning faculty members from giving promotional talks or accepting personal gifts, travel, or meals from industry and placing strict limits on the income faculty can earn from consulting, joining boards, and other work with industry while publically disclosing payments of more than $5,000. Johns Hopkins has addressed this issue by prohibiting gifts, entertainment, and food; barring sales representatives from patient care areas; only allowing invited sales representatives into their facility; and requiring donations to be made to the institution rather than individual doctors (31). Stanford University School of Medicine has made public its faculty members' income from consulting with outside groups and royalty payments for inventions (32).

Institutions that address institutional as well as individual conflicts may well be ahead of the curve. In January 2011, the OIG reviewed the NIH grant process and concluded that there are currently no federal requirements that grantee institutions identify, report, or manage actual or potential institutional conflicts (33). Since 1995, there have been federal regulations regarding investigators' and researchers' conflicts of interest and requiring that those conflicts be managed, but the report found a dearth of guidance—and written policies and procedures at the grantee institution level—to address institutional conflicts. The report concluded that the NIH lacks information on institutional conflicts and their impact on NIH-sponsored research and recommended new regulations to address these issues. Additional activity in this area can be anticipated as members of congress, particularly Senators Grassley and Baucus, continue to advocate for aggressive oversight.

Given the number and types of entities, ranging from industry associations to medical societies to health care institutions and even state and federal government that are involved in crafting rules regarding conflicts of interest, physicians need to stay constantly on top of these requirements. As this area has become increasingly complex, the best advice may be to remain cognizant of the changing landscape and seek appropriate guidance when necessary.

BEST PRACTICES

Advancing health care goals and improving patient care depends in part on close collaboration between health care professionals and industry. As these relationships become increasingly complex, it is more important than ever to insure that actual or perceived conflicts of interest are appropriately addressed. The integrity of the relationship between patient and physician must always be preserved. At the same time, avoiding even the appearance of a conflict and abiding by the increase in transparency requirements helps maintain public—and patient—trust.

The first step is awareness. Be vigilant about activities that, by their nature, may lead to a perceived conflict. In so doing, retain common sense and put yourself in the shoes of the public. A good test for any activity is "what would this look like as a headline in tomorrow's newspaper?"

Be educated about these emerging requirements. There are many sources for information. Begin with your local or national medical society. Both AdvaMed and PhRMA maintain public Web sites full of accessible information about their respective code requirements (21,22). The health care institutions with which you are affiliated may maintain policies that directly or indirectly govern conduct with or disclosure of the industry affiliations of staff, so make sure that applicable policy manuals are checked. Finally, read the fine print of any grant that you may be involved with to make sure you are knowledgeable about any conflict or disclosure requirements.

Another consideration is transparency. To meet this requirement, think about what a typical patient would want to know. Transparency helps provide information to make informed decisions, maintain trust, and minimize conflicts. Expect to see increasing activity in this regard. Transparency is here, so carefully consider industry relationships and funding through the lens of public disclosure.

Finally, keeping up with developments and emerging requirements is important. To avoid making any missteps, stay up to date on what your industry partners and the institutions that you work for require. Don't be blindsided by the specter of public disclosure but instead embrace it as a way to increase the information available to members of the public as they make that all-important decision of who they chose to provide their health care. Ultimately, all of us—the public, the medical community, and industry—will benefit.

HIGHLIGHTS

- Conflict of interest is present when a responsible individual has private circumstances that influence the normal progression of their professional tasks or trust. These conflicts may include financial interests but may also relate to other benefits or outcomes.
- Continuing collaboration between health care professionals and industry is essential to the advancement of health care through innovation, so it is essential to manage conflicts appropriately.
- Disclosure of conflict is the key element to maintaining trust and objectivity.
- Conflict of interest can occur in publishing, in research, in CME, and in the practice of medicine. Various organizations have created guidelines to help manage conflict of interest including the ICMJE, NIH, IOM, ACCME, and the federal government.
- Institutions, through their investments and business interests, can also be subject to conflict of interest problems.
- Medically related industry including medical device manufacturers and the pharmaceutical industry should have internal policies in place to meet legal and ethical guidelines designed to minimize and manage conflict of interest. These policies should encourage the creation of intellectual property and should strive to separate marketing efforts from educational and developmental endeavors.
- Specialty societies including the American Academy of Otolaryngology—Head and Neck Surgery have created guidelines to help maintain the highest standards of professionalism with regard to conflict of interest.

INDEX

(Note: Page numbers followed by *f* indicate figures; those followed by *t* indicate tables.)

A

Aarskog syndrome, 1635–1636
Abbe flap, in lip reconstruction, 1797, 1798, 1799*f*
Abdominal injuries, secondary survey of trauma, 1103–1104
Abductor spasmodic dysphonia, 1032–1033
Ablative resurfacing lasers, 2866–2867
Ablative therapy, 2622
Abrasions, soft tissue injuries, 1109
Abscess(es)
  cerebellar/temporal lobe, 2444
  epidural, 580–581, 581*f*
  odontogenic infection
    buccal space, 773, 773*f*
    dentoalveolar, 771, 772*t*
    submandibular space, 773, 774*f*
  orbital, 576
  periosteal, 2444
  retropharyngeal, 169, 169*f*
  subdural, 581, 581*f*
  subperiosteal, 575, 576*f*
Absorbable suture material, 22
Accent method, voice therapy, 1050
Acetaminophen, 45–46
Achalasia, 854–855, 855*f*
Achondroplasia, 1636
Acinic cell carcinoma, salivary gland, 1765–1766, 1765*f*
Acne rosacea, 3215, 3215*f*
Acoustic neuroma, 213, 213*f*
Acoustic rhinometry, 366, 455–456
Acoustic stapedial reflex measurement, 2279–2280
Acoustic transformer theory, 2466
Acoustic voice analysis, 1072, 1072*f*
Acquired immunodeficiency syndrome. *See also* Human immunodeficiency virus infection
  hairy cell leukoplakia, 743
  lymphoma, 2039
  otologic manifestations, 2520
  Sjögren syndrome, 705
Acral lentiginous melanoma, 1741. *See also* Malignant melanoma
Acrocephalosyndactyly, type I, 1622–1623, 1623*f*
Actinic cheilitis, 3212, 3215*f*
Actinic keratoses, 1726–1727, 1727*f*, 3212
  treatment of, 3224
Actinomycosis, 287–288, 287*f*
Adaptive immune system, 382–383
Adductor spasmodic dysphonia, 1032–1033
Adenocarcinoma, 2047
  ceruminous, 2369
  salivary gland, 1766
    polymorphous low-grade, 1766
Adenoid(s). *See also* Adenotonsillar disease, in children
  enlargement of, 1460*f*
Adenoid cystic carcinoma, 192*f*, 1992*f*, 2047, 2369
  MRI, 154, 155*f*–156*f*
  salivary gland, 1765, 1765*f*
  tracheal tumors, 1996
Adenoidectomy, 2225
  adenotonsillar disease, in children, 1437–1438
  pediatric rhinosinusitis, 1459–1460, 1460*f*
Adenoma
  ceruminous, 2368
  pleomorphic, 2369
  salivary
    basal cell adenoma, 1764
    malignant, 1766–1767, 1766*f*
    pleomorphic adenoma, 1760–1762, 1762*f*
    warthin tumor, 186*f*
  thyroid, 2120
Adenoma sebaceum, 3217, 3217*f*
  treatment of, 3227
Adenomatoid odontogenic tumor, 2104–2105
Adenomatous tumors, of middle ear, 2370–2372
Adenotonsillar disease, in children
  clinical practice guidelines, 1440–1441, 1441*t*
  clinical presentation
    adenoids, 1434
    hypertrophy, 1433–1434
    infections, 1433
    tonsils, 1434–1435, 1435*f*
  complications, 1439
  contraindications, 1438–1439
  controversy, 1440
  embryology
    components and properties, 1431, 1432*t*
    ICA, 1432
    palatoglossus muscle, 1431
    palatopharyngeus muscle, 1431
    pharyngeal pouch, 1430
    structure of, 1430
    Waldeyer ring, 1431, 1431*f*
  epidemiology, 1430
  immunophysiology, 1432
  management
    infection/inflammation, 1435–1436, 1436*t*
    sleep disorders/breathing, 1436–1437
  neoplasia, 1433*t*, 1442
  outcomes, 1436*t*, 1438
  peritonsillar abscess, 1439–1440
  surgical techniques
    adenoidectomy, 1437–1438
    tonsillectomy, 1437
Adenotonsillar surgery
  pediatric otolaryngology, 1300–1301
Adenotonsillectomy, 2225, 2225*f*
Adenovirus, 1433
Adrenal glands
  adrenal insufficiency, 259
  Cushing's syndrome, 259–260
  pheochromocytoma, 260
  primary aldosteronism, 258–259
  secondary aldosteronism, 259
Adrenal insufficiency, 259
  preoperative management of, 33–34, 34*t*
Adrenocorticotropic hormone, 258–259
Adson forceps, 22
Advanced trauma life support, 1212
Adverse event, 3373
Adynamic ileus, 40
Aerodigestive tract
  congenital anomalies of
    pathophysiology
      hypopharyngeal/laryngeal, 1308
      nasopharyngeal obstruction, 1306, 1308*f*
      oral, 1306–1307
      oropharyngeal, 1307, 1308*f*
      tracheobronchial and esophageal, 1308–1309
    postnatal diagnosis
      CT scanning, 1311
      flexible endoscopic evaluation of swallowing, 1310–1311, 1311*f*
      functions of, 1310
      hypopharyngeal/laryngeal, 1313–1314, 1313*f*, 1315*f*
      nasopharyngeal obstruction, 1311–1312, 1312*f*
      oral, 1312–1313, 1312*f*
      oropharyngeal, 1313
      physical examination, 1309–1311

Aerodigestive tract (*Continued*)
tracheobronchial and esophageal, 1314–1316, 1315*f*
ventilating bronchoscope, 1311, 1312*f*
prenatal diagnosis, 1309, 1309*f*–1310*f*
treatment
hypopharyngeal/laryngeal, 1320–1321, 1320*f*–1321*f*
nasopharyngeal obstruction, 1316–1318, 1316*f*–1318*f*
oral, 1318–1319, 1319*f*
oropharyngeal, 1319–1320, 1320*f*
principles of, 1316
tracheobronchial and esophageal, 1322–1324, 1322*f*–1324*f*
ingestion injury
chest radiograph, 1405, 1405*f*
clinical presentation, 1400
complications, 1401–1402, 1402*f*
diagnosis and treatment, 1400–1401, 1401*t*
disc battery, 1406, 1406*f*
foreign-body aspiration, 1402–1403
mass effect, 1405
mechanism of, 1399–1400
treatment, 1404
upper esophageal sphincter, 1405, 1405*f*–1406*f*
workup, 1403–1404, 1403*f*–1404*f*
Munchausen syndrome, 1407
Afferent pupillary defect, midface fracture, 1213
Agency for Health Care Quality and Research, 3375
Aging. *See also* Elderly patients
